The onset was described as abrupt by 48 (96%) of the patients, as insidious by 2 (4%). On direct questioning of those reporting an abrupt onset a history of mild prodromal symptoms for from 1 to 14 days (average 6 days) was obtained in 26%. Vague tiredness, "seediness," lack of the usual desire for food, and mild depression or irritability were admitted to have preceded the more acute symptoms. The early features of the acute stage of the disease were shivering, malaise, and lassitude, followed by anorexia, headache, feverishness, flushes, chills, and profuse sweats. Sometimes these symptoms were not severe enough to prevent the patient from carrying on with duty for several days before reporting sick. Most patients were detained in the unit sick bay for observation before being transferred to hospital.

Dating the onset of the disease from the reported presence of symptoms suggesting fever, the cases reached hospital at various stages, as shown in Table I.

TABLE I.—Stage of Disease on Admission to Hospital

Day of Disease on Admission	No. of Cases	% Total
1	2	4
2	11	22
3	12	24
4	11	22
5	8	16
6	2	4
7	3	6
8	—	—

The frequency of various symptoms in the present series is shown in Tables II-V.

Toxaemic Symptoms

TABLE II—Frequency of Various Symptoms of Toxaemic Origin

Symptom	No. of Cases	Frequency %
Fever	50	100
Malaise	50	100
Lassitude	50	100
Anorexia	50	100
Shivering	37	74
Chills	29	58
Sweating	23	46
Flushes	26	52
Facial pains	15	30
Backache	10	20
Weakness	7	14
Body soreness	5	10
Aches in joints	2	4

The duration of pyrexia in hospital averaged 5.9 days (range 0-13 days); the total duration from the onset of symptoms suggesting fever averaged 8.6 days (range 1-16 days). The pyrexia in 8% was mild in degree (99-100.8° F.), in 22% moderate (101-102.8° F.), and in 70% high (103° F. and over). The fever was continuous (oscillations less than 2° F.) in 14%, continuous remittent (oscillations 2° F. or greater) in 84%, of whom one-third showed fever of hectic remittent type, and intermittent in 2%. Temperatures over 105° F. were observed in 2 cases, and over 104° in 15. Defervescence was by lysis in 86% of the cases, by crisis or pseudocrisis in 14%. Marked clinical improvement occurred when the temperature became normal. A transient secondary rise was seen in 16% of cases. Patients with hectic remittent temperature were the most severely ill clinically. Six patients received sulphadiazine and one penicillin with no obvious effect on the temperature or general condition.

As a rule the pulse rate followed the temperature, though showing a tendency to relative bradycardia. In 28% the pulse did not exceed 100 at any stage; in 50% it ranged between 100 and 120 at the height of the fever; in 22% it rose above 120, only one case showing a rate above 140.

Headache, malaise, lassitude, and anorexia were the most constant symptoms. Patients wished to be left alone, and desired the sleep which headache often prevented. Anorexia occurred in all cases—usually slight, in some almost complete. In general, however, most took food without forcing even at the height of the fever. Sweating was profuse in many, occurring night and day and necessitating frequent changes of clothing. Shivering, later followed by flushes and chills, was

attacks lasting as long as three hours. No rigors were seen. Body pains were an outstanding complaint in 10% of the cases; patients complained that they felt as if they had been "kicked and thrown around."

Respiratory Symptoms

TABLE III.—Frequency of Various Respiratory Symptoms

Symptom	No. of Cases	Frequency %
Cough	47	94
Sputum: Mucoid	23	46
Mucopurulent	7	14
Blood-stained	12	24
Rusty	2	4
No sputum	6	12
Pain in chest	23	46
Shortness of breath	3	6
Dyspnoea	1	2
Epistaxis	3	6

The respiratory rate was little affected, and dyspnoea was seen in only one case. Cough, though present to some degree in 94% of cases, was not an outstanding feature. It occurred occasionally at onset, but more commonly appeared about the fifth day, and tended to be more pronounced after the temperature had fallen. In the early stages the cough was short and dry, occasionally paroxysmal, and frequently very distressing by virtue of its effect in exacerbating headache. Later a small amount of sputum was produced—seldom more than 1 dr. (3.5 c.cm.) per day, except in cases with associated bronchitis, which produced up to 1 oz. (28.4 c.cm.) daily. In cases in which the sputum was blood-stained the amount of blood varied from slight streaking to almost pure haemoptysis. Blood-streaked sputum was seen mostly in the more severe cases with hectic remittent fever, and appeared at any stage of the disease, but usually after the temperature had subsided. The sputum was cultured weekly in all cases. Pneumococci (untyped) and *Micrococcus catarrhalis* were the most frequent organisms; haemolytic and non-haemolytic streptococci and *M. tetragenus* were also found.

Chest pain occurred at some stage in 23 of the 50 cases. In 16 it was pleuritic in type, and in 7 it was described as a dull ache over the affected area of the chest. A pleural friction rub was detected in 26% of patients complaining of pain in the chest.

Neurological Symptoms

TABLE IV.—Frequency of Various Neurological Symptoms

Symptom	No. of Cases	Frequency %
Headache: Frontal	44	88
General	6	12
Restlessness	13	26
Dizziness	11	22
Depression	6	12
Confusion	5	10
Insomnia	2	4
Prostration	1	2
Meningism	1	2

Headache was the outstanding and characteristic feature of the disease, and was present with varying intensity in every case. In 80% it was violent, continuous, frontal in location, and "splitting" in character, and was aggravated by movement, coughing, or straining. Retro-ocular pain and generalized occipital and temporal headache also occurred. The intense headache and profound lethargy in some gave a picture suggesting encephalitis. Meningism was present in one case. Three cases in the epidemic, not included in this series, had lumbar puncture performed, with normal findings.

Alimentary and Urinary Symptoms

TABLE V.—Frequency of Gastro-intestinal Symptoms

Symptom	No. of Cases	Frequency %
Constipation	20	40
Nausea	12	24
Vomiting	10	20
Dryness of mouth	4	8
Sore throat	2	4
Diarrhoea	1	2

Gastro-intestinal symptoms were few and mild, and subsided after the first few days. Constipation was frequent in the early

stages, and vague abdominal pains were present in a few cases. Anorexia, already noted, was a constant prodromal symptom.

Frequency of micturition without demonstrable cause was encountered in one case. Four patients reported "dark urine" before admission.

Physical Signs

On admission abnormal physical signs in the chest were often few or lacking.

TABLE VI.—Frequency of Abnormal Physical Signs in the Chest

Sign	No. of Cases	Frequency %
Diminished movement	2	4
Impaired percussion note	11	22
Diminished air entry	12	24
Consolidation	1	2
Localized crepitations	48	96
Generalized rhonchi	18	36
Pleural friction	6	12

One-third of the cases had generalized bronchitic rhonchi on admission. The characteristic and most valuable sign was a localized patch of persistent, sticky, fine, or medium crepitations, which were first heard on the average in 5.7 days (range 1–13 days) from the onset of acute symptoms. In some cases crepitations were scanty, difficult to detect, and evanescent during examination; in others they were heard in profuse showers. In two cases no crepitations could be detected at any stage, but typical opacities were apparent on radiological examination. Diminished movement, reduced air entry, and impaired percussion note were seldom of great value in locating the lesion. Cases showing generalized bronchitic rhonchi tended to produce frothy blood-stained sputum during convalescence. Serial skiagrams showed that the disappearance of abnormal physical signs did not imply full radiological resolution. Pleural effusion was not observed in the cases in this series. Other physical signs noted are listed in Table VII.

TABLE VII.—Frequency and Type of Clinical Signs other than Respiratory

Signs	No. of Cases	Frequency %
Palpable glands:		
Posterior cervical	30	60
Axillary	14	28
Inguinal	9	18
Epitrochlear	5	10
Spleen:		
Palpable and tender	14	28
Palpable, not tender	4	8
Liver:		
Palpable and tender	6	12
Tenderness	14	28
"Rose spots"	17	34

Glands were often found to be enlarged on admission, but they subsided early in convalescence. The posterior cervical group were those most commonly affected. The glands were small, firm, discrete, and not tender. The spleen was just palpable in 18 and slight liver enlargement was detected in 6 of the 50 cases. Scanty small pink macules fading on pressure similar to the rose spots of typhoid fever, were observed in 34% of the cases in the early stages. They appeared in crops on the chest, back, and flanks, and occasionally on the shoulders. Neurological and cardiac signs were minimal. A lowered blood pressure was observed in some of the more toxic cases. Mild hyperaemia of the pharynx was usual on admission.

Laboratory Investigations (Major J. M. Slaveley)

Blood was withdrawn weekly for laboratory investigation. Blood slides were examined for malaria in all cases on admission and frequently repeated in cases with a previous history of malaria or very high pyrexia. No positives were reported. Owing to technical difficulties, shortage of materials, and the pressure of routine work the number of tests on each patient had of necessity to be limited. Blood counts, sedimentation rates, Takata-Ara and cephalin-cholesterol flocculation tests and heterophil antibody and cold agglutination tests were done where possible once a week.

Leucocyte Counts.—A total of 311 counts at various stages of the disease were done in the 50 cases. Mean absolute values of the various cellular elements during the course of the disease

are set out in the accompanying Graph. This shows a slight initial polymorph response followed by a depression, which was maximal at the end of the first week. The subsequent rise in both polymorphs and lymphocytes reached a peak at the 16th to 18th days. The differential counts showed a slight relative

Mean absolute values of white cells at different stages of the disease

lymphocytosis after the initial period. In some of the two-daily groups the numbers were not great, but the trends revealed seemed significant. Scattergrams showed a wide range of values. Eosinophils showed no characteristic changes. Six patients had more than one count in excess of 6% of the total, the highest absolute values being 3,300 (21 and 4,600 (29%) per c.mm. Both these cases were subsequently shown to be harbouring intestinal parasites.

Red Cells and Haemoglobin.—All counts and estimations were done by van Slyke's copper sulphate method. The red cell counts are therefore approximate only. A haemoglobin value of 15.5 g. per 100 c.cm. was taken as 100%. There appeared to be a tendency towards a mild anaemia with a macrocytic trend. At some stage of the disease 60% of the cases showed red cell counts below 5,000,000 per c.mm.; only two were below 4,000,000 per c.mm. The mean cell volume tended towards the upper limits of normal, with a range from 88 to 95 c.u. The haemoglobin concentration fell below 14 g. per 100 c.cm. in 56% of the cases at some stage of the disease. The two cases with red cell counts below 4,000,000 per c.mm. received iron; otherwise no treatment was given for the anaemia, and spontaneous recovery occurred during convalescence.

Total plasma protein estimations showed no significant changes. Differential estimations were not possible with the staff available.

Sedimentation Rate (Wintrobe—corrected—normal, 0-9 mm./hr.).—At various stages of the disease 234 estimations were made on blood from the 50 cases. When possible estimations were made on admission and thereafter at weekly intervals. Findings are given in Table VIII.

TABLE VIII.—Average Sedimentation Rate in Successive 7-day Periods

Day of Disease	No. of Estimations	Rate in mm./hr.
1-7	21	19
8-14	41	18
15-21	41	13
22-28	45	8
29-35	49	7
36-42	36	7

The highest value obtained was 45 mm./hr. on the 12th day. This was exceptional. The sedimentation rate in the early stages averaged 19 mm./hr., and was of some value in differentiating from malaria in severe and from hepatitis in mild cases.

Latato-Ara Reaction.—This test was performed 63 times between the 5th and the 24th day of the disease. A moderate positive (+ - 0) was obtained in only one patient, who was also convalescent from prolonged hepatitis. The results were consistently negative in sera giving a positive cephalin-cholesterol flocculation reaction.

Cephalin-Cholesterol Flocculation Test.—This test was performed 211 times in the 50 cases, at various stages of the disease. The cephalin was prepared in the hospital laboratory and the stock cephalin-cholesterol mixture kept in refrigeration. Uniformly negative results were obtained using this mixture in tests of 40 normal individuals. On two occasions the tests with the locally made reagents were set up against a similar series using control reagents obtained from an American central laboratory. Identical results were obtained; these are set out in Table IX. The flocculation was graded in terms of 0, +, ++, +++, and ++++, at 24 and 48 hours. The "mean positiveness" referred to in the tables indicates the sum of positive signs at 24 and 48 hours respectively divided by the number of cases in each group.

TABLE IX.—Mean positiveness of Cephalin-Cholesterol Flocculation at Successive 7-day Periods

Day of Disease	No. of Tests	Mean Positiveness	
		24 Hours	48 Hours
1-7	13	0.7	1.3
8-14	31	0.8	1.4
15-21	46	1.2	2.4
22-28	46	1.7	2.7
29-35	42	1.8	3.0
36-42	33	1.5	3.0

In general flocculation was insignificant early in the disease and slight during pyrexia; it increased rapidly after convalescence had been established in the second week, thereafter rising slowly. This trend was particularly well shown in the group of cases with hectic remittent fever, who were the most numerous. Many cases still had strongly positive cephalin-cholesterol flocculation reactions on discharge.

Heterophil Antibody Reaction.—This test was performed 143 times on the 50 patients at different stages of the disease. Horse cells were used, varying in age at the time of the test from 1 to 7 days. The findings are therefore not exactly comparable in successive tests, though extreme care was exercised in the preparation for and execution of the test to make it as uniform as possible. A titre of 1:448 (horse cells) was taken as being undoubtedly a significant positive. By this standard 18 cases (36% of the total) gave a positive result at some stage of the disease. A further 13 cases (26% of the total) showed a titre of 1:224. The stage of the disease at which the first positive was obtained was not constant. The average was on the 24th day, the earliest positive being on the 6th day (1:1,792) and the latest first positive on the 49th day (1:896). The highest titre found was 1:7,168 on the 33rd day. In general the titre gradually declined in cases which were positive early, while late-appearing positives showed an increasing titre and a subsequent decline.

Comparing the clinical course of the 18 cases showing a heterophil antibody titre of 1:448 or more at some stage with the remaining 32 cases the following points were noted.

(1) **Fever.**—The average duration of pyrexia was not significantly different. The fever showed a slightly greater tendency towards the remittent rather than the continuous type in the cases with positive heterophil antibody reactions.

(2) **Malaria.**—A past history of malaria was obtained in 10 of the 18 cases with titres 1:448 or above and in only 3 of the remaining 32. None of the cases was taking mepacrine at the time of the illness, and repeated blood slides were negative for malaria parasites.

(3) **Physical Signs.**—A greater incidence of lymphadenopathy, enlargement of the spleen, and rose spots was found as under:

Heterophil Antibodies	Cases	Palpable Spleen	Palpable Glands	Rose Spots	Blood-stained Sputum
Titre 1:448 or more	18	10	15	8	4
Titre below 1:448	32	3	15	9	6

(4) No undue increase in the total leucocytes or in cells of the lymphocytic or mononuclear series was noted in the cases giving positive heterophil antibody reactions. The undulations observed in the mean absolute values of the various white blood cells conformed with the trends already described, though the number of cases is obviously too small for reliable averages.

(5) The flora of the sputum were similar.

(6) No significant differences were apparent in radiological findings.

(7) All cases had negative Laughlen reactions. The Kahn test was performed on 10 cases showing high heterophil antibody titres, with negative results.

Urine

A specimen of urine was examined when the patient was admitted and subsequently at weekly intervals on the day after the investigations on the blood. In all, 204 specimens were examined from the 50 cases. The findings are set out in Table X.

TABLE X.—*Urinary Findings* in Successive 7-day Periods*

Day of Disease	No. of Tests	Bile Pigment (Fouchet) (% +)	Methylene Blue (% +)	Urobilinogen (% Increased)	Albumin (Trace to +) (% Total)
1-7	45	47	76	24	22
8-14	24	27	55	24	9
15-21	39	17	34	0	0
22-28	21	10	14	0	0
29-35	39	3	5	0	0
36-42	36	0	6	0	0

Bile pigment seldom exceeded a trace by Fouchet's method. Six of the 20 cases with liver enlargement showed biliruria. The methylene-blue test was performed as a routine in view of recent emphasis placed by some American workers on its diagnostic value in infective hepatitis. It appears to be non-specific, to show no direct correspondence with the Fouchet test, and to be potentially misleading if regarded as of diagnostic value in any single condition. A reducing substance (Benedict) was transiently present in 3 cases. Increase in urobilinogen and albuminuria were obviously related to the febrile phase of the disease. The Laughlen test was performed in all cases, with uniformly negative results.

Gold Agglutinins.—Tests (119) for cold agglutinins were done at all stages from the 3rd to the 33rd day. The first 12 tests were carried out both with the patient's own corpuscles and with washed fresh Group O corpuscles. The remainder were done with fresh washed Group O cells alone. Three cases showed agglutination in dilutions of 1:20 and one case in 1:40. The remainder were negative at all stages.

Radiological Findings (Major G. L. Rolleston)

Postero-anterior and lateral films were taken in every one of the 50 cases. In the great majority of cases it was possible to demonstrate a localized area of increased density, which was interpreted as a parenchymatous infiltration, between four and six days after the onset of symptoms. Characteristic x-ray findings were: (a) The localization of the lesion to one or more broncho-pulmonary segments. The infiltration was found to be pyramidal in shape, with its bases situated peripherally and its apex pointing towards the hilum. (b) With the exception of two cases which were "hilar" or central in location the lesions were all peripheral. (c) The shadows cast by the infiltration could be described as hazy mottled densities. Structural accentuation and homogeneous densities were also observed in a few cases.

Several other radiological observations were of importance. Of these 50 cases, 30 showed involvement of segments in the lower lobes, 16 in the upper lobes, and 6 in the right middle and left lingular lobes—lesions in the lower lobes therefore predominating. The importance of the lateral film was shown by the following facts: (1) Infiltrations which in the postero-anterior projection appeared hilar in origin were usually situated in the apical segment of the lower lobe and were therefore peripheral lesions. There were only two exceptions to this finding. (2) In several instances the postero-anterior film showed no lesion, but the lateral projection demonstrated the infiltration either behind the heart or in that portion of the lung situated behind the summit of the diaphragmatic dome.

Definite elevation of the diaphragm involving the posterior portion was demonstrated in three cases of posterior basal infiltrations. This finding was interpreted as resulting from a combination of lobular atelectasis and the splinting action of that portion of the diaphragm. There was no radiological evidence of any hilar adenopathy; either in the early or in the resolving stages of the lesion. In this series no case showed evidence of pleural effusion. In cases subsequently encountered during the epidemic five instances of pleural effusion were observed. Two were generalized unilateral effusions, two encysted paravertebral effusions, and one was interlobar.

Regular serial examination was not possible owing to shortage of films. Examination carried out six weeks after the onset of symptoms revealed that resolution was complete in the majority of cases.

Classification of the Radiological Findings

1. Broncho-pulmonary segments involved (62 segments affected in 50 cases; percentages refer to segmental frequency):

	Right	Left
Upper lobe:		
Apical	3 (4.8%)	2 (3.2%)
Subapical	6 (9.7%)	5 (8%)
Axillary	—	—
Pectoral	—	—
Middle lobe:		
Anterior	3 (4.8%)	1 (1.6%)
Axillary	1 (1.6%)	1 (1.6%)
Lower lobe:		
Apical	4 (6.4%)	2 (3.2%)
Subapical	—	4 (6.4%)
Posterior basal	9 (14.5%)	9 (14.5%)
Axillary	1 (1.6%)	—
Anterior	1 (1.6%)	—
Hilar	—	2 (3.2%)
Zones:		
Upper	1 (1.6%)	—
Middle	2 (3.2%)	2 (3.2%)
Lower	1 (1.6%)	2 (3.2%)

2. Type of shadow cast by the lesion: Hazy mottled density, 43 (86%); homogeneous density, 2 (4%); structural accentuation, 5 (10%).

3. Diaphragmatic elevation: 3 (6%).

4. Degree of lesion: Minimal, 12 (24%); moderate, 33 (66%); extensive, 5 (10%).

5. Bilateral infiltrations: 4 (8%).

6. Cases with two or more segments involved: 12 (24%).

Differential Diagnosis

Most cases were referred to hospital with a diagnosis of pyrexia N.Y.D. or malaria. In the period before the development of characteristic pulmonary signs the diagnosis was often in doubt between malaria, infectious mononucleosis, fevers of the enteric group, meningo-encephalitis, "influenza," and infective hepatitis, by virtue of the prominence of one or other of the diverse clinical features already described. Cases showing pulmonary signs on admission had to be differentiated from other forms of pneumonia. The absence of leucocytosis, pulmonary consolidation, or dyspnoea, and the relative bradycardia were helpful in diagnosis. During the epidemic some cases not included in this series presented with identical prodromal symptoms and onset but with a leucocytosis of from 15,000 to 30,000. Such cases received chemotherapy with apparent benefit despite the fact that the subsequent radiological examination showed strictly segmental lesions. It was presumed that these cases were primarily atypical pneumonia with secondary infection in the affected lobule.

Treatment

All cases were isolated until the temperature had been normal for one week or until productive cough had ceased. The R.A.F. orderly and hospital librarian developed primary atypical pneumonia during the course of the epidemic. All attendants wore mask and gown. Patients were kept in bed until they had been at least ten days afebrile and until abnormal physical signs were no longer detectable. A few preferred to be propped up on pillows; the remainder lay flat. A light diet in the febrile phase was generously supplemented when the appetite returned in convalescence.

the flaps of aponeurosis which have been raised from the anterior surface of the patella before the bone is removed. Catgut or kangaroo tendon is not sufficient. In the present series the interval was at first closed by fascial strips, but these were found to be unnecessary, and silk alone was used. Later still, unbleached linen thread was found to be more satisfactory and to give less tissue reaction.

2. It must be appreciated that the injury is really a major injury to the knee-joint and, as in all such injuries, quadriceps wasting will be rapid. Quadriceps insufficiency develops during a period not of weeks but of days, and half an inch of wasting in a few days may take months of physiotherapy to regain after the operation. For this reason early operation is essential—usually on the fifth day after the accident, or as soon as the skin over the operation site is sufficiently healthy. For a similar reason the patient must be got up early after the operation, and, if a wool splint is used, this can be done with impunity on the fifth or sixth day, the patient walking with two sticks or between two chairs, using his own quadriceps actively, but not at first bending the knee. Back splints or plaster must be avoided at all costs. Post-operative physiotherapy is not as a rule necessary, but may be used when required. The operation must be performed by the bloodless method.

Case Reports

Case 1.—Male aged 35. Twelve years previously he fell and sustained a transverse fracture of the left patella with separation of the fragments. These were removed and the gap in the aponeurosis was closed with interrupted sutures of silk. Fourteen days after operation he was discharged from hospital, and four weeks later returned to work. On examination the function of the knee was normal; range of movement full, with no loss of power; no symptoms. The patient says he can distinguish no difference between the two limbs. Skiagram shows no osteoarthritic changes. No deformity.

Case 2.—A plumber aged 51 fell and sustained a comminuted fracture of the right patella. Fragments were removed and the interval repaired with silk. Now, after 13 years, he has full function, no limitation of movement, normal power, no limitation of full extension, and no deformity. Skiagram shows no osteoarthritic changes. He has been doing his full work as a plumber ever since, and says he can distinguish no difference between the two limbs.

Case 3.—A domestic servant aged 36. Transverse fracture—moderate separation. Fragments removed; interval repaired with silk. Back at work in one month. Now, 10 years after her operation, she says she can notice no difference between the two legs; if anything, the other one is not so good, as she gets rheumatism in it. Movements full; power normal; no deformity; no loss of full extension. She can run upstairs. Skiagram shows early osteoarthritis with lipping of patella in other knee. In the affected knee no osteoarthritic changes were seen.

Case 4.—Female aged 40. Sustained a transverse fracture of the left patella, which was excised 7 years ago, and a transverse fracture of the right patella, which was excised 5 years ago. In both cases quadriceps expansion was sutured with silk. The function is full; no limitation of extension; power normal. No O.A. changes in either knee. A little deformity in the right knee, but not in the left. Doing her full work as a packer.

Case 5.—Female aged 52. Transverse fracture with wide separation 9 years ago. Fragments removed and interval sutured with silk. Discharged home 4 weeks after operation. Now function and movements are full; no weakness, no symptoms, and no deformity. Skiagram shows no O.A. changes.

Case 6.—Male aged 58. Comminuted fracture of patella. Fragments removed, repair by silk 6 years ago. Now doing full work as a navvy. Can run upstairs. Can detect no disability whatever. Function, power, and movement full; no deformity. Skiagram: No O.A. changes.

Case 7.—Female aged 32. Transverse fracture 9 years ago. Is now in Land Army doing full work. Passed Grade 1 (knee not noticed). Function now full; no symptoms, no deformity; range of movement full, extension full. Skiagram: No O.A. changes.

Case 8.—Male aged 40. Transverse fracture with separation operation 5 years ago. Sutured with thread. On examination power, range of movement, and extension now full. A grocery porter, he does a full day's work, cycling all day, and notices nothing wrong with his knee.

Case 9.—Male aged 67. Transverse fracture through old wired patella; wire septic, and sinus through skin wired and patella excised. Interval sutured with catgut 8 years ago. Now has impaired function—flexion to right-angles only. Knee a little deformed; power impaired; extension full. The patient says that the knee is weak, but

is much improved since the operation (excision). Before, he could not stand or walk on it. Skiagram shows no O.A. changes.

Case 10.—Female aged 64. Fell 5 years ago and sustained a comminuted fracture of the patella. Repair with thread. Now she complains of some weakness and difficulty in getting upstairs. Function is good, extension full. She can walk well, and does her shopping. There is no pain. She can stand on the affected foot with the knee bent. There is gross rheumatism in the opposite hip. No deformity of knee. Skiagram: No O.A. changes.

Case 11.—Male aged 68. Transverse fracture of patella. Patella removed 5 years ago. Now complains of weakness and difficulty in getting upstairs. Walks with a stick. Movements are full; there is no detectable weakness of the quadriceps; no deformity; extension full. A frail man, older than his years. Not working.

Case 12.—Male aged 62. Comminuted fracture of left patella. Bone removed 7 years ago. He is now working full time as a labourer. He says that from the time he recommenced work he has noticed no difference in the two limbs. In fact, he was not quite sure that the injured knee was not the better. No deformity; extension full; range and power normal. Skiagram: No O.A., but slight O.A. lipping of patella of other knee. He demonstrated that he could run upstairs.

Case 13.—Female aged 35. Old transverse fracture with refracture after suture 9 months later. Patella excised 10 years ago. Repair with thread. Movements full; no weakness; no deformity; extension full. She says that the knee does not interfere with her life in any way.

Case 14.—Male aged 63. Transverse fracture with wide separation. Excised 10 years ago; sutured with silk. Now extension and range of movement full; no deformity. Skiagram: No O.A. changes. The patient complains of slight stiffness going up and down stairs. He says he can walk 10 to 15 miles without getting tired, and can do most things without difficulty, but for years has been restricted in his activities by an old injury to the right hip. Skiagram shows old O.A. of hip supervening on what appeared to be an adolescent coxa vara deformity.

Case 15.—A carpenter aged 57. Sustained a transverse fracture of the left patella 10 years ago and a transverse fracture of the right patella 8 years ago. In both cases the injury was due to an accident—the first at work, the second a road accident. In both cases the fragments were removed and the interval repaired with thread. Examined 10 and 8 years after his accidents, he says he has got on well. He can find no difference from before the accidents. Both legs are equally good. He does his full work as a carpenter. Movements full, extension full; no deformity; no loss of power; no thickening of the knees. Skiagram: No O.A. changes. He demonstrated that he could run upstairs with ease.

Case 16.—Female aged 58. Transverse fracture with separation 5 years ago. Was walking five days after operation. Now says that knee is as good as before the accident; can do all her own housework and can kneel without discomfort. Walks without limp. Extension full; power and movement normal; no deformity. No O.A. changes on x-ray. No symptoms.

Case 17.—Female aged 57. Transverse fracture 5 years ago with separation of fragments. Repair, using thread. Now on examination extension is not full; can get upstairs with difficulty. The knee looks a little ugly; it is still improving. Otherwise, function normal. In this case there was gross separation of the fragments. The other leg is weak.

Case 18.—Male aged 62. Sustained a transverse fracture at work 12 years ago. The fragments were excised and the interval closed with silk. From the first this patient, a postman, was not co-operative, and the question of compensation was always present. He is now walking well; there is no deformity; movements full. Complaints of some weakness. Skiagram: Negative for O.A.

Case 19.—Female aged 53. Sustained a comminuted fracture of the left patella 14 years ago. Fragments were removed and interval repaired with fascia. Now says that there is not the slightest difference in the two sides. She can run upstairs, and has done so for many years. She says she can walk miles. Extension, power, and movement full. Skiagram: No O.A. changes. No deformity; no symptoms.

Case 20.—Male aged 30. Transverse fracture with separation. Removal 11 years ago; sutured with silk. He has been in the Army—accepted A1; operation scar not noticed. Before the war he played professional football after the operation. Movements full; no deformity; extension full. Skiagram: No O.A. changes. He says the knee is perfect. He can run upstairs.

Case 21.—Male aged 60. Stellate fracture; removal and suture with thread 6 years ago. Patient says he would not know that the operation has been done. He works as a navvy. He was back at work 18 weeks after the accident. He can run upstairs, and no loss of power or function could be detected. A skiagram showed no O.A. changes in the joint.

Samples of gravy were taken in some cases when cooking-water had been used in its preparation. From data obtained in this way and from the results of the experiments of Allen and Mapson (1944), Olliver (1941), and Jenkins (unpublished), the vitamin C contents of the vegetables were calculated.

The most accurate method of estimating the influence of the volume of cooking-water on the vitamin C content of green vegetables is to weigh the cooked vegetable and measure the volume of the water after cooking. It was not possible to make these measurements in the present survey, and a less accurate method had to be adopted—namely, to judge whether the vegetable was a quarter, half, or completely covered by the cooking-water. This is not wholly satisfactory, since the important ratio is the final volume of water to the weight of cooked vegetable, and this will vary with the size of saucepans even when the degree of covering is kept constant. Assuming that the pan is of a size conveniently filled by the vegetable, then the volumes of water necessary to cover the vegetable completely, half, or quarter would, according to calculations, permit retentions of the order of 20, 40, and 60% of the vitamin C content of the raw vegetable. The loss during keeping hot or reheating of green vegetable was judged from the experiments to be 50% per hour. No account was taken of whether the greens were placed in cold water and gradually brought to boiling point, or were plunged directly into boiling water, as this factor does not appear to be important in affecting the vitamin C loss in cooking on the domestic scale (Jenkins, unpublished), but it is important when large amounts of vegetables are being cooked (Macrae, 1944). In the case of root vegetables, oxidation and extraction during boiling were assumed, on the basis of the experiments mentioned above, to cause a fall to 50% of the raw value, with further destruction at the rate of 50% per hour if kept hot, unless the vegetables had been mashed, when the rate of destruction was about three times greater (Jenkins, 1943; Lampitt *et al.*, 1943).

The average vitamin C content of the raw potatoes available at the time of the survey was found by analysing a number of pooled samples obtained from several shops in the districts. The values found (mg./100 g.) were 20 in September and 9 in April. No value for raw green vegetables was obtained, as it was not possible to collect and estimate a sufficiently large number of raw samples to make the result significant for so variable a vegetable as cabbage. A value of 70 mg. per 100 g. was taken as the average value for raw cabbage (Olliver, 1943). The average calculated values are given in Table II.

Results

The results are divided into three parts—first, a small-scale survey carried out in the winter of 1942–3; secondly, 200 samples collected in the industrial cities in Sept., 1943; and, finally, 100 samples from the same cities in April, 1944. Some of the analyses of samples collected during April were carried out by Dr. L. P. Kendal, who has kindly allowed me to quote his results.

The results of the analyses are set out in Tables I and II. The figures obtained for gravies were often anomalous in that

TABLE I.—Results Obtained in Preliminary Survey; Winter, 1942–3

	Nov./Dec., 1942			Jan./Feb., 1943		
	No. of Samples	Vitamin C (mg./100 g.)		No. of Samples	Vitamin C (mg./100 g.)	
		Average	Range		Average	Range
Potatoes	12	10.5	8–16	9	6	3–8
Cabbage	5	22	13–47	1	11	—
Brussels sprouts	4	50	39–68	7	29	17–41

their vitamin C content exceeded that of the vegetable water from which they were prepared, indicating the presence of reducing substances other than vitamin C, formed during cooking, which interfere with the estimation (Mapson, 1943). Since the method of assaying vitamin C separately from these substances is time-consuming it was not possible to apply it, and the results obtained on gravies have not been quoted. A few samples of other vegetables (e.g., swedes and onions) were analysed, but the numbers were too small to justify publication.

TABLE II.—Found and Calculated Vitamin C Values from Industrial Cities

	September, 1943						April, 1944					
	No. of Samples	Vitamin C (mg./100 g.)					No. of Samples	Vitamin C (mg./100 g.)

Discussion

The first survey of 1942–3 was on so small a scale that by itself no significance could be attached to the results; but the figures suggested that the losses of vitamin C during cooking, in these homes, were not excessive. Forty samples were taken from 21 meals, and, assuming that each meal contained 150 g. of potato and 100 g. of the second vegetable, which are reasonable helpings, all but eight of them provided 30 mg. of vitamin C—that is, the daily requirement suggested by the League of Nations Commission—and, of these eight, only four provided less than 24 mg. Cooking loss was responsible for the low vitamin C in only one of these meals; in another meal the second vegetable was carrots (providing only 2 mg.), and the other two contained no vegetable other than potato. The average content per meal was 43 mg. for November/December and 33 for January/February.

Many of the housewives who provided samples in the two larger surveys had completely covered their green vegetables with water and therefore increased the proportion of soluble nutrients extracted during cooking. A few housewives followed the Ministry of Food's instructions for cooking greens, with the result that their product contained about three times as much vitamin C as the general average. The finding that the vitamin C content of cooked cabbage in spring (35 mg./100 g.) was so much greater than in autumn (13 mg./100 g.) is unexpected, and is probably fortuitous, as only 14 samples were collected in April.

Using the figures obtained in the larger survey, a typical meal, containing potato and greens, was estimated to provide about 28 mg. of vitamin C in September and not less than 20 in April. If the second vegetable were carrots, or if, as sometimes occurred, no second vegetable were served, then the meal would provide only about 15 mg. in September and 7 or 8 mg. in April. These amounts of vitamin C were probably the total day's intake in most families, as typical wartime breakfasts and teas contribute little or no vitamin C. It would seem that propaganda aiming at increasing vitamin C intake should place as much stress on the importance of including green vegetables in meals as on methods of reducing cooking losses.

Many households did not have a cooked meal at home, as all members of the family received a canteen or British Restaurant meal, the vitamin C content of which tends to be low.

Comparison of Found and Calculated Values

Comparison of average vitamin C values of the vegetables as determined by analysis, with those obtained by calculation shows remarkably good agreement for potatoes and fair for cabbage (Table II). The correlation between calculated and determined values for individual samples is, however, low but significant ($r=0.52$ for 38 samples of cabbage; 0.39 for 50 samples of potato in September and 0.59 for 46 samples in March; P is less than 0.01 in all cases). The data collected in this survey therefore indicate that it is not possible to calculate the precise vitamin C content of an individual meal, but that the averages of figures so obtained are in close agreement.

Although it appears not to be possible to calculate accurately the vitamin C content of a meal it is possible to estimate most meals to say whether it is very low or very high. When calculations indicated that a meal contained, say, less than 10 or more than 30 mg. of vitamin C, the analysis usually confirmed this general grouping, but there were many discre-

same technique was employed bilaterally, the signs and symptoms were noticeable only on the left side of the body.

It is of less importance for the purpose of this report to decide whether the partly transient neurological signs and symptoms were due to oedema or haemorrhage. In either case, the symptoms and signs indicated the level of the operative lesion, and it seems that when the section is carried out posteriorly, as in the reported case, no better therapeutical results can be expected than from the conventionally performed operation.

I wish to thank Dr. E. Cunningham Dax and Mr. E. J. Radley-Smith for their helpful criticism.

PRIMARY BENIGN TERTIAN MALARIA AMONG BRITISH TROOPS IN NORMANDY

BY

W. W. MACNAUGHT, M.B., Ch.B.
Colonel, R.A.M.C.

Eight cases of primary B.T. malaria occurred in British soldiers serving in Normandy during August and early September, 1944. These soldiers had never previously served outside the United Kingdom, nor had they ever been in a malarious country. During the period subsequent to disembarkation they all, with one exception, admitted having been bitten many times by mosquitoes, and this man stated that the others sleeping under the same canopy complained bitterly of mosquito bites. In each of the following case records a short account of the onset of the symptoms is given, with a note of the variation of these to indicate the difficulty in reaching the correct diagnosis.

Case I

A young man aged 20, Category A1, attached to a paratroop battalion, was admitted to 77 General Hospital on Aug. 11, 1944, as a transfer from a small hospital, where a blood film had been examined on his admission there and B.T. rings and schizonts with some gametocytes had been found. He gave a very suggestive history of shivering and headache for four days previously. He had never before been out of England and had arrived in France on D Day.

On examination the spleen tip was palpable, but otherwise no other abnormality was found. A repeat blood film showed the presence of B.T. parasites. He was treated with quinine and pamaquin, and made an uninterrupted recovery.

Case II

A man aged 20, Category A1, arrived in France with an R.E. company on June 11, 1944. He was admitted direct from his unit on Aug. 20, diagnosed "infective hepatitis," with a history of pyrexia and headache of three days' duration. He had first reported sick on Aug. 17 and been treated in quarters with simple antipyretic measures until the 20th, when he was admitted to this hospital. His symptoms of headache and fever had begun during a short spell of heat. Several cases of the "effects of heat" had occurred.

On admission his temperature was 106° F. There was a faint tinge of yellow in his conjunctivae; the urine contained no bile, but there was a trace of albumin. Examination of a blood film taken the same evening showed no malaria parasites. A white cell and differential count revealed a leucopenia. Blood culture proved sterile. Examination of heart and lungs showed no abnormality, and the liver and spleen were not palpable. The pyrexia continued intermittently, but no bile appeared in the urine and there were no other positive findings until a repeat blood film late at night on Aug. 23, at the height of his fever, showed B.T. parasites. Quinine was given and the patient made a rapid recovery, with one rigor on the day following the first administration of quinine.

The spleen tip was first palpable on Aug. 23, but by the 25th it was easily felt to two fingerbreadths. The faint yellow tinge in his sclera disappeared; it was probably of haemolytic origin. This soldier had never served out of England before, and the diagnosis was obscured at first by the negative findings. It is noteworthy that at the height of the fever his pulse rate was slow.

Case III

This patient was a man aged 35, Category A1, who had arrived with his A.A. unit in France on D Day, having always previously

lived in England. He was admitted on Aug. 25, 1944, as a transfer from another general hospital with the diagnosis "(i) ? malaria (never been in a malarious region); (ii) ? typhoid," and the following history: (1) malaise 3 days; (2) headache ++; (3) pain under left ribs; (4) generalized aching; (5) fever and sweats. He had been quite well until Aug. 22, and then was exposed to very wet conditions, when the above symptoms developed and progressed. He had had no vomiting, abdominal cramps, or diarrhoea, but had a harsh persistent cough with slight whitish expectoration. A blood film taken before admission had shown no malaria parasites.

On admission his temperature was 104° F.; his face was flushed and he was sweating. He was coughing violently, with little streaks of blood in the expectoration, and this was associated with occasional vomiting. The throat was reddened and the tonsil glands were slightly enlarged but not tender. On examination there were numerous rhonchi in the chest but no signs of consolidation. The spleen was ++ (four fingerbreadths) and acutely tender, otherwise there was nothing abnormal in the abdomen.

A repeat blood film taken on admission showed the presence of B.T. parasites. He was immediately treated with quinine, and by next morning his temperature was normal, and except for a slight rise to 99° F. on the 27th he had no further fever. The spleen gradually subsided, and each day became less and less tender; his cough rapidly improved, and by Sept. 10 it was no longer palpable and there was no tenderness in this area.

Case IV

A trooper of a Recce regiment who had arrived in France about Aug. 10, 1944, Category A1 and aged 19, was transferred to this hospital on Sept. 3 from another general hospital with a history of headache, general aches, and abdominal pain since Aug. 31. A blood film examined on Sept. 1 showed the presence of B.T. parasites—a few rings and amoeboid forms. Quinine 10 gr. (0.65 g.) and pamaquin 0.01 g. were started on that day, when his temperature registered 101° F.

Thereafter he passed through various medical units and arrived at this hospital. Blood films taken here were negative, but this was to be expected, as he had had quinine for two days previously. On admission his temperature was 98.4° F. and he was complaining of headache and pain in the back; there were no other symptoms. On examination no evidence of any other condition was found to account for his temperature, and his spleen was not palpable. He was given a full course of quinine and pamaquin, and except for some sweating has had no further symptoms or fever. He states that he had never before been out of England.

Case V

This patient was a gunner who had arrived in France on July 6, 1944, and had never been out of England before. He was admitted direct from his unit on Sept. 1, diagnosed "P.U.O.," with a history of three days' fever, and headache, abdominal pain, constipation, and general aches. He had been shivering each day though the weather was quite warm. On examination nothing organic was found in any system, but a thick blood film showed numerous B.T. rings and amoeboid forms. The spleen was not palpable. He was treated with quinine and pamaquin, and has made a good recovery.

Since his arrival in France he has been stationed in the same place, where he states there are many mosquitoes and he was frequently bitten by them. He was in a billet in which no other troops had been previously, and no others of his section had ever had malaria or been in a malarious country; he does not know whether this billet had been occupied by Germans or not.

Case VI

A driver in the R.A.S.C., aged 19, Category A1, had arrived in Normandy D+3 Day—i.e., June 9, 1944. He was admitted to this hospital on Sept. 6 direct from his unit, diagnosed "P.U.O.," complaining of slight headache, pain in the small of the back, and general malaise. His temperature was 103.4° F.; there was no obvious cause for the fever. He stated that he had had headaches, with tiredness and loss of appetite, for a week before admission, associated with a clammy sweat at times during this period. He had no previous history of any similar illness and had never before been out of England.

On examination he was pale, with a malar flush. He complained of headache, which was increased on flexing the neck, but there was no rigidity of the neck muscles. Kernig's sign was negative. The fauces were slightly infected, otherwise nothing abnormal was found in any of the systems and the spleen was not palpable. A white cell count on Sept. 7 showed: W.B.C., 7,400 per c.mm. (polymorphs 48%, lymphocytes 49%, monocytes 3%, eosinophils nil); but in slide for differential white cell counts revealed numerous B.T. rings and an occasional gametocyte. On Sept. 8 the spleen was 14 fingerbreadths below the costal margin. Further blood films confirmed the diagnosis with numerous B.T. rings and amoeboid forms and gametocytes.

Treatment with quinine was begun on Sep. 8 and the patient's temperature subsided. During his period in France he had slept under lorry canopies in various places, but for the past three or four weeks had been in one place near the coast, from which one other case of this series was admitted though from a different unit. There were many mosquitoes, but he himself had no recollection of any mosquito bites, though others under the same canopy complained of many. Several of the men of his unit have been in malarious countries but he has no knowledge of their having had malaria. On Sep. 10 the spleen was only just palpable, but was not tender. The patient had a slight rise of temperature to 99° F. on that day, but there had been none since.

Case VII

A sapper aged 37, who had been in France since D+1 Day was treated in this hospital from Sept. 1 to 12, 1944 on account of a very mild pyrexia lasting one day only and responding to rest in bed and an aspirin-phenacetin-caffeine mixture. Two days after his discharge from hospital he had a definite fever, the sclera was faintly yellow, and he was readmitted, with a temperature of 103° F., diagnosed as "infective jaundice". There was no bile in his urine, but a blood film showed numerous BT parasites (ring amoeboid forms, rosettes, and gametocytes) and a degree of anisocytosis suggestive of a moderately long standing condition, but obviously of a subclinical type. The spleen up was palpable and the liver edge could also be felt and was tender. He had never been out of the United Kingdom previously and only one other member of his unit had been in a malarious country, however, the slit trench which he occupied with his friend—Case VIII—was within 50 yards of billets in a village previously occupied by the Germans. He stated that they had many mosquitoes in the slit trench and were frequently bitten.

Case VIII

Another sapper of the same unit, who had always shared the same slit-trench as his friend Case VII, was admitted on Sep. 16. He too, had never previously been out of the United Kingdom. He stated that he had been quite fit until Aug. 28, when he was admitted to an R.A.F. hospital suffering from fever. This quickly subsided with a simple diaphoretic mixture, and he was discharged to light duty on Sep. 5, but did not feel fit and complained of tiredness in the legs until Sep. 15, when he again reported sick with fever, vomiting, abdominal pain with tenderness in the right hypochondrium, and a faint icterus of the conjunctivae. He, too, was admitted with the diagnosis of infective jaundice.

On examination there was a faint tinge of yellowness of the sclera, the spleen was just palpable and tender, and the liver edge was also palpable and tender. There were no signs in any of the other systems. The urine did not contain bile. A blood film showed BT malaria parasites. He has responded well to quinine and pamaquin.

Discussion

Although these are records of the rare occurrence of malaria in Normandy the local French doctors have no knowledge of any such occurrence in this region. A large number of the troops in the invasion force have had previous service in malarious countries, and it is officially reported that *A. maculipennis* is to be found in this locality. The infection of these mosquitoes may have been via that route or by the Germans who were stationed there before our arrival, for we know that prisoners taken have had earlier service in Africa. Temperature charts of the above cases mostly gave a very typical picture of a malarial fever.

At the time of the admission of these patients many other cases of fever were being admitted with similar symptoms, these eventually developed symptoms leading to their correct diagnosis: e.g., (i) acute intestinal infections with fever—before the actual onset of the diarrhoea, (ii) infective hepatitis—with nausea but no other symptoms at first except fever, (iii) one case of lymphocytic meningitis, with headache and fever as the only symptoms, (iv) "effects of heat" with headache and fever only.

Although most of these patients were serving in units with troops who had seen service in malarious countries the infection did not arise until at least three weeks after they had left England, which is against its having occurred before embarkation. Many apparently primary attacks have been noted in other cases, but these had served in malarious countries previously and were therefore excluded from this record.

My thanks are due to Major J. V. Dacie, R.A.M.C., and Major J. C. K. Reid, R.A.M.C., for the pathology involved, and to Brig. E. Bulmer and Col. E. P. N. Creagh for permission to publish this article.

Medical Memoranda

A Method of Closed Anastomosis

The method to be described affords a simple means of performing anastomosis between an two hollow viscera under closed conditions. It requires no special appliances and is of general application. It is equally applicable to end-to-end and to lateral anastomosis and it can be used in a variety of access. It prevents gross swelling of the peritoneum at the state of the operation and the final result should be a secure aseptic junction.

The method consists in the introduction of a temporary guarding suture which maintains closure of the viscera until completion of the anastomosis, when it is removed. The simplest case is that of resection of a portion of the bowel followed by end-to-end union. Narrow crushing-clamps are placed across the bowel which is divided between them by an endothermy needle or cautery. Close below the clamp on the portion to be retained a thick catgut suture is inserted preferably with an eyles needle, penetrating the bowel completely four or five times (Figs. 1 and 2). On removing the clamp

closure is maintained by holding the suture taut when the bowel may conveniently be slid along the suture to narrow the opening somewhat (Fig. 3). The bowel on the other side of the portion to be removed is treated in the same way and the two bowels are then brought together and united by one or more layers of Lembert sutures. Finally, the guarding sutures are cut short on one side and removed. A little manipulation ensures a free lumen and a secure anastomosis is result.

In the case of a lateral anastomosis, such as a gastro-enterostomy, a blunt pointed rod is passed through each viscus deep to the site of the proposed opening, as suggested by Panrett, and a guarding suture is inserted between each rod (Fig. 4). The rod is now cut out by either a cautery knife or an endothermy needle and closure is maintained as before by traction on the guarding suture. If as is convenient the two viscera have already been joined together by a posterior layer of Lembert sutures, all that is now required is the completion of an anterior layer and the withdrawal of the guarding sutures. A little manipulation ensures a free opening and there appears to be no fear of haemorrhage from the cut margin provided a cautery or endothermy has been used and the Lembert sutures take a firm grasp of the muscle coats. The only special appliance required is the rod and for this a knitting needle of steel for a cautery, or of plastic for endothermy, is satisfactory.

The simplicity and cleanness of gastro-enterostomy carried out by this method are remarkable. In relation to the large bowel it has an important application in the resection from the abdomen of carcinoma of the recto-sigmoid junction or in favourable cases of the ampulla followed by immediate end-to-end anastomosis greatly simplifying this otherwise difficult operation which may by this means be carried out with facility and security.

H. S. SOUTAR, F.R.C.S.

Thyrotoxicosis in a Mongol

As I can find no recorded instance of thyrotoxicosis in a Mongol I think the following case worth publication.

CASE RECORD

A typical mongolian umbilic, aged 22, was admitted to Levenshoe Hospital on Feb. 6, 1941. The patient's sister stated that she had noticed a swelling in the patient's neck early in 1939, and in December, 1940, observed that she tended to choke when swallowing solid food. The patient "always seemed on the warm side and

disliked sunshine." In July, 1939, her weight, which was normally 6 st. 11 lb. (43 kg.), fell to 5 st. (32 kg.).

I first saw the patient on June 6, 1941. She then complained of severe abdominal pain, which may be a feature of thyrotoxicosis, as described in Price's *Medicine*, 6th ed., p. 488. The eyes were prominent and staring. There was marked enlargement of the thyroid gland, especially the right lobe. The pulse rate was 100 a minute (she had a persistent tachycardia of 90-110 at this time). The B.P. was 118/60. The apex beat was felt in the fourth left interspace $3\frac{1}{2}$ in. (8.9 cm.) from the midline. The rhythm was regular and the heart sounds normal. There was marked pulsation of the carotid arteries and a thrill and to-and-fro bruit, best marked where the lateral lobes of the thyroid glands crossed the carotid vessels and maximal on the right side. There was a fine tremor in the fingers. The skin was moist and warm. Her weight was then 6 st. 12 lb.

In July, 1941, she was transferred to the University College Hospital E.M.S. Wing at Leavesden, when Dr. Trotter estimated the B.M.R. Once it was raised by 47% and once by 54%. After 18 days on Lugol's iodine 10 m. (0.6 c.cm.) t.d.s. the B.M.R. fell to plus 30%. The sleeping pulse rate then averaged 70. In Sept., 1941, the blood cholesterol was 276 mg. per 100 c.cm. A sugar-tolerance curve gave a fasting level of 75 mg., rising to 280 mg. one hour after taking 50 g. of glucose and reaching 240 mg. at the second hour. Glycosuria was present during the test.

An electrocardiogram taken in Jan., 1945, showed a sinus tachycardia, rate 128 a minute, with pulsus alternans and wide ventricular extrasystoles suggestive of myocardial damage.

Re-examination of the patient on Oct. 7, 1945, revealed an increase in weight to 7 st. 12 lb. (50 kg.). The eyes were no longer prominent and staring, and the thyroid gland was much smaller, being just palpable. The pulse rate was 70 and the B.P. 124/80. The apex beat was in the fourth left interspace $3\frac{1}{2}$ in. from the midline. There were frequent extrasystoles. The heart sounds were normal, with a pulmonary systolic murmur. The pulsation in the carotids had diminished, the thrill was no longer felt, and a faint to-and-fro bruit was audible on the right side only. The tremor in the fingers was less marked.

I am indebted to Dr. R. M. Stewart, medical superintendent, Leavesden Hospital, for his assistance and for permission to publish the case. I am also indebted to Dr. W. Trotter, University College Hospital, for the B.M.R. estimations.

LEO GILCHRIST, M.D., M.R.C.P., D.P.M.,
Acting Deputy Medical Superintendent, the Fountain
Hospital, Tooting Grove.

Obstructed Transmesenteric Hernia

Transmesenteric hernia is an uncommon cause of intestinal obstruction. A review by Cutler and Scott (1944) reported only 48 cases occurring in the literature. For this reason, and because the case throws some light on the aetiology, the following example of the condition is reported.

CASE HISTORY

A nursing sister of the Royal Naval Nursing Service, aged 27, was on night duty in a hospital ship with the British Pacific Fleet, when she was suddenly seized with an acute abdominal colic. This was soon followed by vomiting. I was asked to see her, and, apart from the fact that she certainly had a midgut-loop colic with vomiting, nothing abnormal was found on abdominal examination. I decided to observe her for an hour or two, but the condition became worse, the pain increased, vomiting became more marked, and she was clearly in great distress. Obstruction of unknown origin was diagnosed; the true nature of affairs was not appreciated pre-operatively.

Four hours after the onset of the pain the abdomen was opened by a right paramedian incision. There was some straw-coloured free fluid in the peritoneal cavity. The caecum was lax but the jejunal coils were distended. She was found to have a hole in the mesentery 3 ft. (90 cm.) from the ileo-caecal valve, with about 1 ft. (30 cm.) of ileum herniated through. The herniated gut was not strangulated, and was readily reduced. The margins of the opening in the mesentery were smooth and rounded, and the hole measured approximately 2 in. by 2 in. (5 by 5 cm.); this was closed with a continuous thread suture. The appendix was retrocaecal and therefore nowhere near the defect, and it showed no signs of past or present inflammation. It was removed.

Convalescence was marred by somewhat persistent vomiting and the excessively high atmospheric temperature, the ship being anchored within 120 miles of the Equator at the time; but after 14 pints (8 l.) of saline and glucose the patient's condition rapidly improved, and she was up on the sixth post-operative day. The wound healed soundly, and she has since remained symptom-free.

The case is of interest, first, in that it is apparently the 49th reported case of transmesenteric hernia causing obstruction; secondly, because it has been claimed that trauma and inflammation are aetiological factors. There was no history of trauma in this case, and no evidence of infection. The smooth rounded appearance of the hole indicated clearly a congenital origin.

Reviews

FERTILITY IN MARRIAGE

Fertility in Women. By Samuel L. Siegler, M.D., F.A.C.S. With a foreword by Robert Latou Dickinson, M.D. (Pp. 442; illustrated. 35s.) London: Wm. Heinemann Medical Books, Ltd.

Fertility in Men. By Robert Sherman Hotchkiss, B.S., M.D. With a foreword by Nicholson J. Eastman, M.D. (Pp. 216; illustrated. 25s.) London: Wm. Heinemann Medical Books, Ltd.

In these days, when attention is again focused on the subject of fertility in general, and on the high incidence of sterile and relatively unfruitful marriages, the appearance of these books is timely. They are companion volumes, and, although each is an entity in itself, few will wish to read one without the other. Between them they present a very complete picture of what is at present known concerning male and female fertility and those factors which influence it, adversely or otherwise. They constitute one of the best surveys of the subject to be found in the English language, and, as such, they will be welcomed by all who are interested in the study and treatment of infertile marriage. In both books the outlook is wide and scientific, normal physiology is dealt with at some length, and fertility receives as much attention as infertility. The authors have managed to achieve considerable uniformity in a style and a method of presentation which are attractive. Their statements are cautious and by no means dogmatic. Each chapter is accompanied by an extensive bibliography, and there are few matters pertaining even remotely to the subject to which reference is not made. In matters of production these books are well up to the high standard which we have come to expect in those emanating from the United States of America, and the illustrations, some in colour, are not only plentiful but exceptionally good. The reproductions of radiographs call for special praise.

Dr. Siegler's work is the larger and more detailed of the two. More than 100 pages are devoted to the physiology of the female sex organs, and mainly to ovulation, its time of occurrence, determination, etc. The clinical approach to the female partner of an infertile marriage is well described, as are all the special tests and investigations, including even laboratory techniques such as the method for estimating pregnanediol in the urine. Every form of treatment, from vaginal douching to x-ray therapy to the pituitary gland and salpingostomy, is set out in full detail. The section on endocrine therapy of various kinds is particularly helpful. The value and limitations of this type of treatment and the important part played by the receptor tissues in determining their response to hormones are well stated.

The book by Dr. Hotchkiss is smaller and rather less satisfying. This is perhaps more a reflection on the limitations of present-day knowledge of male fertility than on the book and its author, who has himself been responsible for a good deal of original work on the subject. Again we find the same attention to detail in the description of the clinical side of the problem and of the various investigations, including laboratory techniques, testicular biopsy, etc. Semen analysis and the significance of its results receive full consideration. It is made clear that the treatment of male infertility is not always so hopeless as is often imagined, but it is made equally clear that there are many gaps in our knowledge—particularly in regard to the causation, and therefore prevention, of such a high proportion of cases of impaired male fertility. It is a pity that the author has seen fit to omit impotence from consideration. Even though potency and fertility are separate issues, they are often closely related. Impotence sometimes plays a part in infertile marriages, and always presents a difficult problem to the clinician. It probably deserves a chapter to itself. Cryptorchidism and other anatomical faults also merit more attention.

Gone are the days when sterility and fertility in either man or woman were looked upon as absolute states, and it is now realized that very few individuals are fully fertile or sterile. All grades of fertility occur in both sexes, and low fertility in one partner of a marriage may be compensated by high fertility in the other. In any case of infertile marriage it is therefore unreasonable to consider the fertility of the man except in

relation to that of his mate, and vice versa; this is made abundantly clear by Dr. Siegler and Dr. Hotchkiss, which makes it all the more surprising that they should have decided to present their subject-matter in two volumes rather than one. The division has resulted in some overlapping and repetition, though every effort has been made to reduce this to a minimum. Moreover, it must have been difficult to apportion some of the material, and this has led to a few anomalies, thus all the characteristics of spermatozoa are dealt with under male fertility—with the exception of the behaviour of spermatozoa in the environment of the female genital tract, which is relegated to the other book. Under which of the two titles should artificial insemination be considered? We leave it to readers to guess how the authors answer this question.

A combination of these two books would not result in too cumbersome a volume—particularly if the chapter on ovulation was abbreviated to some extent and the chapter on abortion, which is the least satisfactory and is somewhat irrelevant, were omitted. In their place, however, we make a plea for the inclusion of a section on male impotence.

This criticism is deliberately constructive, because with some modification and elaboration these books might well become a standard work on the subject. Even as they are they will achieve a well-deserved popularity, and their intrinsic merit is such that they will easily survive these qualifications to our praise. It is to be hoped they will thrive on them.

PRE-SCHOOL CENTRES IN AUSTRALIA

Pre-School Centres in Australia. Building, Equipment and Programme. The Lady Gowrie Child Centres. By J. H. L. Cumpston, M.D., and Christine M. Heing, Ph.B., M.A. (Pp. 232. No price given.) Department of Health, Commonwealth of Australia.

This remarkable volume gives all possible information about the six Lady Gowrie Child Centres which have been set up in the State capitals of Australia. Profusely illustrated, it shows the children themselves in their various occupations from games and lessons to afternoon sleep. Apparatus and equipment are depicted, and architects' ground plans show how the different centres have been planned and built. Detailed schedules—reminiscent, in their completeness, of Army forms 1098—list everything which such buildings contain. At the same time descriptions are given of experimental work by the staff in the estimation of the intelligence and character of their under-five charges.

This is not a book to be read through, but as a mine of information for all those who are concerned with the public and even the private care of "the under-fives" it must prove invaluable. Everyone is impressed with the importance of the first half-decade of life in the formation of future character, and the care of this section of the population was one of the major problems of evacuation; it behoves us, therefore, in our future planning to be very sure what we want to do with these children if they cannot be in the best place—that is, in their own homes—and so this volume is particularly opportune, especially for officials of local authorities and everyone concerned with the placement of young children. All such should have it on their shelves for constant reference.

A FRENCH WORK ON PENICILLIN

Revue M.P. Bernard Bureau,
et al. 17p. 224, illustrated.
Flammarion.

It is perhaps not surprising that at least two books for the guidance of users of penicillin should have appeared in the U.S.A. before any on this subject has been forthcoming in the country of its origin. That France should furnish the next is more unexpected, for supplies of penicillin in that country were exceedingly scanty less than a year ago, and the experience gained since then cannot have overtaken that of British and American workers, who entered this field so much earlier. It is therefore, much to the credit of four members of the staff of the Pasteur Institute and Hospital—R. Martin, F. Nitti, B. Bureau, and J. Berrod—that they have produced a book, *La Pénicilline et ses Applications Cliniques*, which should be a serviceable guide to the clinical use of penicillin, and ensure that the reader thoroughly understands the nature of the treatment he is giving. Although the text is based very largely on the work of foreign authors, it is embellished by numerous instructive case

histories from the authors' own experience. The clinical section, which occupies much the greater part of the book, deals first with infections due to staphylococci, streptococci, and pneumococci, and then with meningitis, infections of the lungs, gonorrhoea and syphilis, war wounds, oto-rhino-laryngology, and ophthalmology. Introductory chapters give an adequate account of theory and laboratory methods. There are many good illustrations and a bibliography of 662 references.

VECTORS OF SCRUB TYPHUS

Acute and Chronic Transmission of Typhus in India, Australia and the Far East. By Susan Finnegan, Ph.D., B.Sc. British Museum (Natural History), Economic Series No. 16 (Pp. 76. 1s. 6d.). 1945.

Scrub typhus was a major military problem during the war in South-East Asia and the South-West Pacific. Because few had articulated the theory and first-hand acquaintance with the disease was so rare, a great demand for information about it and its vectors arose. Hence Dr. Susan Finnegan is intended to make readily accessible to those in the Tropics modern knowledge concerning the vectors which are believed to carry the disease, it also summarizes information about ticks which carry other forms of zoonotic infection. The book gives a great deal of useful and otherwise inaccessible data.

Because of the military importance of scrub typhus, it was obviously wise to push ahead with the production of this book (even if it only appeared some months after the end of the Japanese war) although it was known that research then in progress was soon likely to make it obsolete in many details, and although security regulations deprived the author of the opportunity to include much material concerning control. With all this information now becoming available, it is to be hoped that before long a further edition will be produced. An unfortunate misprint on page 11 characterizes scrub typhus as giving a negative OXK Weil-Felix reaction.

Notes on Books

We have received from the United States Information Service (American Embassy, Grosvenor Square, London, W.) a reprint of the *Lancet* Clinic Number of the *Surgical Clinics of North America* published by W. B. Saunders in Philadelphia and London. This gives a full record of two symposia—one on gynaecological surgery, the other on thyroid surgery. The opening paper of each collection is by Dr. Frank H. Lahey.

A third edition of *Clinical Biochemistry*, by Prof. ABRAHAM CANTAROW, M.D., and Lieut.-Cmdr. MAX TRUMP, Ph.D., has been published by W. B. Saunders Company (Philadelphia and London; 32s. 6d.). The book originally bore the title *Biochemistry in Internal Medicine* but that was changed for the second edition, noticed in our issue of Jan. 6, 1940. Progress in biochemistry during the past five years has called for extensive supplementation and revision of the text and a new chapter is included on hormone assay and endocrine function by Dr. A. E. Rakoff. The book remains a readable and informative guide to biochemistry as applied to medicine. It does credit to the Department of Physiological Chemistry and the Laboratories of Biochemistry at Jefferson Medical College and its associated hospital in Philadelphia.

Dr. B. N. GHOSH's *Treatise on Hygiene and Public Health*, of which earlier editions have been noticed in this column, deals with the matter mainly from the point of view of practice in the Tropics. It first appeared in 1912, and the eleventh edition (Calcutta: Scientific Publishing Company; Rs. 12/8 or 21s.) is dated August, 1945. The good features of earlier issues are preserved, and the author has made a considerable number of changes in view of the experience accumulated mainly as a result of war conditions. There is a new chapter, on social medicine, written by Dr. J. B. Grant, Director of the All-India Institute of Hygiene and Public Health, and Dr. Ghosh has provided a new chapter on camp sanitation. This edition is sure of a welcome in India, and in this country it will find readers among those who are directly or indirectly concerned with the study of tropical hygiene.

The new edition of E. O. JORDAN and W. BURROWS's *Textbook of Bacteriology* (W. B. Saunders; 35s.) is the fourteenth to appear since 1903—a reliable testimony to merit. Some of its features are the thoughtfully written introductory chapters, bacterial physiology and immunity being particularly well dealt with, the remarkably fine photographs of bacterial colonies, and the adequate space devoted to viruses and pathogenic fungi. Helminthology has also been included in the new edition: this is a questionable change, since by the standard set by the rest of the book this subject calls for a volume to itself.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 16 1946

THE MINISTER LISTENS

A correspondent recently observed that there seemed to be little doing on the medico-political front. Is this apparent inactivity because of apathy, or because of a spirit of defeatism in the face of a Government that can whip up a majority of 200 to enforce any legislative measure it wants? Doctors, it is true, share the general weariness of the spirit that descends on everyone in the immediate post-war phase, made less easy to resist in the present gloom of austere living on short commons in front of fires that burn very low. As a people we have missed the elation of victory—the short-lived compensation for years of endurance. As a profession which has had to negotiate with two wartime Ministers of Health, we are faced with a peacetime Minister who consults but does not negotiate or, in the ordinary sense of the word, discuss. To listen to what another man has to say is not discussion. Discussion, to quote a dictionary definition, is: "examination (of a matter) by arguments for and against." Democracy, someone has said, is discussion, and deprived of this stimulus the uncontrolled democrat feels deflated. The sparks that fly in free discussion of a controversial question often illuminate dark corners and bring to light matters that one side or the other would wish to conceal or have overlooked.

Mr. Bevan has not followed the example of his predecessor by publishing his proposals as a White Paper. He has, however, put them before various interested bodies, including the Negotiating Committee. The Committee has been precluded from circulating these to the medical profession. It has examined them and re-examined them in the light of previous decisions and of the principles drawn up by it. It has not been able to obtain the views of various professional groups, or of the profession at large, because the proposals are confidential. If they constitute the Bill the Minister of Health is to place before Parliament, then clearly he cannot make them public before Parliament has seen them. He may claim to know the views of the profession. He may even reflect that Ministers of Health have a habit of remaining in office barely long enough to make their mark on legislation. It may be that he is urged on by a Cabinet on which the *Observer* last Sunday made this criticism: "In its doctrinaire passion for nationalizing as much as possible as fast as possible, it was minding everybody's business but its own." But the fact remains that Mr. Bevan has refused to negotiate. He has received the Negotiating Committee and has listened to its comments on and criticism of his proposals. And he has withheld his response until it can be backed up by a majority in the House of Commons.

Mr. Bevan is acting within his rights as a Minister of the Crown. But he would not be acting outside them if he freely exchanged views across the table with a group of men chosen by the medical profession to represent it in negotiation. He has himself said that no health service can be run properly except with the whole-hearted co-operation of the doctors of this country. Co-operation means working together, and working together means, among other things, talking together. From this fruitful source of enlightenment we are at present debarred. This is not a promising start. Although the present phase of secrecy is highly disconcerting to those doctors who want to plan for their future—whether to enter practice or to leave it—nothing can be done to help them until the Bill is published. With the Bill in front of it the medical profession will have to decide what is to be its attitude to it as a whole, and will then have to examine its details. If the profession can agree on its attitude to the Bill, whether of disapproval or approval, and can preserve unity in action, then it need have no fears for the future. Legislators can legislate, but only doctors can provide the service.

THE SUBSTANCE CALLED "BAL"

Throughout the war much valuable work in discovering an antidote to arsenical vesicants was carried out in the Biochemistry Department at Oxford and the Chemical Defence Research Station of the Ministry of Supply at Porton. The veil of secrecy has now been lifted, and Peters, Stocken, and Thompson¹ have given an account of their work on the substance variously known for security reasons as "BAL" (British anti-lewisite) and OX217. The new substance is 2,3-dimercapto-propanol (CH₃SH.CHSH.CH₂OH). It is a penetrant oil, and in pure state is about 6% soluble in water. The reaction with lewisite is:

The idea which initiated the work occurred in 1923 to Walker,² who, following the discovery of glutathione by Hopkins, showed that arsenicals such as diphenyl-chlor-arsine abolished the fixed —SH in muscle tissue and skin, thus interfering with glutathione catalysis. Similar work was done in the United States independently by Voegtlin and his colleagues,³ who came to the conclusion that the toxic action of arsenic in living cells was due to its reaction with certain thiol compounds present in protoplasm. Further work confirmed the idea that arsenicals attack —SH groups, and in 1931 Cohen, King, and Strangeways⁴ showed that thioarsenites of type R.As(SR') were dissociable in alkaline solution. Peters⁵ showed that dichlorodiethyl sulphone, a vesicant, acted upon the enzyme system oxidizing lactate in the brain by poisoning the pyruvate component, as does the enzyme inhibitor iodoacetic acid, and, since this is also a weak vesicant, he thought the vesicant effect might be related to this action

¹ *Nature*, 1945, 156, 616.² *Biochem. J.*, 1928, 22, 292.³ *Publ. Hlth. Rep. Wash.*, 1923, 38, 1911.⁴ *J. chem. Soc.*, 1931, 3043.⁵ *Nature*, 1935, 138, 327.

Research in Oxford⁶ has also shown that pathological changes in the brain in thiamin deficiency were due to partial failure of the "pyruvate oxidase" enzyme system, owing to deficiency of aneurin pyrophosphate. Dickens⁷ and others⁸ had shown that iodoacetate readily combined with —SH compounds. Thus the idea arose that the activity of arsenicals was due to an attack upon some essential SH component in the pyruvate enzyme system, and this formed the starting-point in the search for an antidote to lewisite.

During the war much work was done, but unfortunately it all had to be reported in secret documents to Government Departments, both here and in the United States and Canada. Peters, Stocken, and Thompson¹ soon confirmed the theory described above by showing that, *in vitro*, trivalent arsenicals produced a 50% inhibition of the activity of the pyruvate enzyme system, while, *in vivo*, poisoning with arsenite led to an elevation of the blood pyruvate level, similar to that occurring in vitamin B₁ deficiency. In spite of this no monothiol or dithiol compound would protect against lewisite or arsenite in either enzyme or animal tests; but Stocken and Thompson finally solved the problem when they found that, after treating aqueous solutions of keratine (the reduced product of keratin) with lewisite, the arsenic content of the resulting lewisite-keratine was correlated with the thiol content of parent protein and independent of the concentration of lewisite above a limiting value. This led them to the hypothesis that the high toxicity of trivalent arsenicals was due to their ability to combine with essential —SH groups to form stable arsenical rings, and caused them to investigate the therapeutic possibilities of the dithiols, in the hope that they would form more stable ring compounds than the tissue thiols.

After testing toluene dithiol and ethane dithiol BAL was discovered, and it proved highly effective in stopping the toxic action of lewisite upon the pyruvate oxidase system, and, further, it was found that besides being able to prevent the toxic action of lewisite it could reverse it. Animal experiments showed that guinea-pigs and rats seriously ill after two hours' contamination with lewisite could be saved, and on human volunteers at Porton it was found that vesication could be prevented as late as one hour after contamination, at a time when erythema and oedema were already present—in fact, these were less twenty-four hours after treatment than they were at the start. Further, both at Oxford and Porton and in the United States, experiments have shown that BAL will save a rabbit's eye up to twenty minutes after contamination. It was also noted that this treatment was followed by a marked increase in the excretion of arsenic in the urine. Repeated applications of BAL can induce sensitivity, and small amounts placed on the skin of men caused an erythema lasting up to two hours as well as lacrimation. Animals with renal damage showed no difference in their response to large doses, but those with hepatic damage showed toxic signs. In rats it was found to have a toxicity of 110 mg/kg (LD₅₀). Many similar substances were investigated, but all proved more toxic, with the exception of "BAL intrav," which was dis-

covered by another British group, and on which so far no reports are available.

Chiesman¹⁰ reported that, in factories manufacturing lewisite, pain after contamination of the eye is relieved by BAL ointment, and if it is applied within two minutes of the contamination a complete cure may be expected, though it causes marked blepharospasm. He stated that on the skin it will prevent vesication and relieve the effect if applied within a few minutes, and will mitigate the severity up to one hour after contamination. In the United States it was found possible to develop a solution suitable for intramuscular injection 10 benzylpenicillin in arachis oil was used as the vehicle. It thus became possible to treat complications of arsenical therapy, such as dermatitis and encephalitis. Doses as high as 4 mg/kg at four-hourly intervals may be given, and the results have proved much better than with any other treatment. The compound of mapharside with BAL is more dissociable than that with lewisite, and the presence of excess of BAL is needed for its stabilization, but increased arsenic excretion in the urine was also noted with mapharside. In various experimental animals with arsenic poisoning Lovatt Evans¹ found some prophylactic and therapeutic action from BAL.

While BAL seems to be a complete antidote to arsenical war gases, it has no effect on mustard gas, and therefore has not rendered chemical warfare a thing of the past. However, it is also a great discovery in the treatment of arsenic poisoning and, since other metals form very stable and indissociable compounds with dithiols, it may prove an antidote in other metallic poisoning. The discovery also forms an important advance in theory. Pathological damage is brought about by the partial blocking or denaturation of an enzyme system, and, further, this pathological change is proved to be reversible.

BUMBLEDOM IN ESSEX

From Porton, no patent from the county of Essex (other than a certificate of the certificate of a relieving officer or a doctor in need of relief by reason of accident or sudden illness needing immediate admission to hospital) may be sent for admission to the Haymeads Hospital without my previous consent having been obtained in writing. You will, of course have to decide in individual cases whether treatment is of such extreme urgency as to necessitate admission without my consent."

This is part of a circular letter from the county medical officer for Essex to general practitioners living near the Essex-Herts border who may want to send their patients to Haymeads Hospital, Bishops Stortford, which is in Hertfordshire. This hospital was upgraded during the war, and under the E.M.S. arrangements was used by patients in the "natural hospital area." The war over, local authorities are back at their old game of Tom Tiddler's ground, and the county medical officer, reluctantly no doubt, is called upon to help them to play this according to the old-established rules. Accompanying his letter to the practitioners concerned is an application form from the Public Health Department of the Essex County Council. On this the practitioner has to say that he has examined Mr., Mrs., or Miss . . . , and has to state the nature of

⁶ *Lancet*, 1936, 1, 1161

⁷ *Biochem J*, 1933, 27, 1141

⁸ Quastel J. H., and Wheatley, A. H. M., *ibid.*, 1932, 26, 2169

⁹ *Rapport, C. R. Soc. Biol., Paris*, 1933, 112, 790

¹⁰ *Brit. J. Med. Sci.*, 1944, 2, 109

the complaint. He then has humbly to ask the county medical officer for Essex to arrange for the admission of his patient to a hospital in Hertfordshire. So that the county medical officer of health may decide whether this is really necessary the practitioner is instructed to give brief notes of the case on the reverse side of the form of application. Naturally the C.M.O. does not ask to see the patient. Nor does it appear that he asks for notes so that these should accompany the patient when he goes to hospital. They are, it is presumed, to help him to arrive at his decision about the need for the admission to hospital of a patient he has not seen. This decision "in regard to each case will be notified to you in writing, and if I am in agreement I shall at the same time notify the hospital so that they can make the necessary arrangements for admission." This is what is called administration, and this is the kind of thing that makes the practising doctor shudder when he contemplates the administration of medical services through the unimaginative mechanism of local government. There is no mention in the county medical officer's letter of the medical superintendent of Haymeads Hospital. He at least, although his duties may be primarily administrative, should have a closer knowledge than the C.M.O. of the facilities that the hospital can offer and of its suitability for a patient whose admission is recommended by a local general practitioner. He probably also knows the local practitioner personally, whereas the county medical officer, tucked away in County Hall at Chelmsford, may be in complete ignorance of the persons concerned. It is not doubted that this inept way of handling what should be a simple matter is forced upon the county medical officer, and we hope that he will take the matter up with his authority, so that this modern example of Bumbledom may quickly be brought to an end.

BORNHOLM DISEASE

This epidemic disease, variously known as epidemic pleurodynia, epidemic myalgia, or "the devil's grip," is characterized by violent pain suddenly coming on in the lower part of the thorax and tending to spread to the abdomen. The disease was first described in Norway in 1872 by Daae, and two years later Finsen reported that there had been outbreaks in Iceland in 1856 and 1863. It attracted little attention until Sylvest¹ in 1930 recorded 93 cases between 5 months and 59 years of age, which occurred on the island of Bornholm in the Baltic. Since then many outbreaks have been reported, both in this country²⁻⁴ and in the U.S.A.^{5,6} The disease usually appears in warm weather. The onset is abrupt, with pain in the epigastrium and hypochondriac region which spreads into one side of the chest and is accentuated by breathing. In a recent outbreak Ronald⁷ noted that, in addition to the abdominal muscles, there was particular involvement of the muscles around the shoulder girdle and neck. The affected muscles are tender and swollen, and the disease is accompanied by fever, usually up to 101° F. but sometimes higher; frontal headache is complained of in more than half the cases, and occasionally there are vomiting, diarrhoea, and epistaxis. Paraesthesiae in the arms and hands occur, especially in females. There are rarely any signs in the chest, and the spleen is not enlarged. One or more relapses take place in a quarter of the cases. The tenderness and swelling of the muscles and pain on exertion

may last several weeks or months after the acute attack has subsided. Complications, such as dry pleurisy, orchitis, pericarditis, pneumonia, and otitis media, are on record, but mostly the disease follows a benign course and results in complete recovery. Nichamin⁸ noted a steep reduction in haemoglobin level, and in his eight cases the red cells numbered less than 4 millions. White cell counts seem to vary widely, with no particular differential abnormality. The sedimentation rate is usually raised. The causal organism has not yet been identified, but an agent pathogenic to monkeys has been obtained from the blood, spinal fluid, and nasal washings of human cases of the disease.⁹

From June to November, 1944, 75 cases occurred in a war housing estate adjacent to a large shipbuilding yard on the Mobile River, at Mobile, Alabama.⁵ There were 1,200 apartments reserved for the employees of the shipbuilding firm, and the workers were mostly white people from the rural areas of Alabama and Mississippi. That the spread of the disease is by intimate contact was confirmed by the characteristic distribution of cases in adjoining apartments and within the same household—a fact already stressed by Howard.⁴ The infectivity was variable and not particularly high, but overcrowding in the community was undoubtedly a contributory cause. In 1944 there was an excessive amount of rainfall, with periods of continuously high humidity; warm, moist weather is probably a precipitating factor. Most of the patients were under 30 and 64% were females, but these facts were related to the distinctive nature of the industrial population on the island. The patient smitten with the disease, although reassured about his recovery, is unable to work for an indefinite time. Such disability, when multiplied in an industrial community like that described above, has an effect on industrial efficiency. It is necessary to assess the incapacity associated with an illness and also to appreciate the economic loss which it entails, and by these standards Bornholm disease is not to be neglected.

TESTOSTERONE PROPHYLAXIS OF MAMMARY CANCER

A major outcome of cancer research in recent years has been the recognition that many tumour types are closely dependent upon specific hormonal changes for their inception and, in some cases at least, for their subsequent growth. These facts, and the substantial contribution already made by oestrogen therapy to the management of carcinoma of the prostate, have very naturally raised much interest in the question whether hormone antagonism either direct or indirect, may be used as a practical measure of alleviation or control. This is especially so in carcinoma of the breast, mostly because of the well-defined part which oestrogens are known to play in the causation of mammary cancer in mice, but partly, too, on account of the presumptive connexion between some of the chronic mastopathies, which may involve an abnormal sensitivity to oestrogen, and cancer of the breast in man.

Although testosterone can certainly be regarded as showing a limited form of biological antagonism to the action of the female sex hormone in experimental carcinogenesis, too much should not be made of the point, nor can the matter be regarded as in any way simple. The experimental evidence is that such antagonism—measured by the capacity to prevent cancer of the breast in mice in which it can be determined by oestrogen action alone—is not readily made apparent, although it has in fact been

demonstrated by the use of dosages of testosterone which are sufficiently high and maintained for a long enough period. Although the production of breast cancer may be retarded by this means, there is little evidence that testosterone produces any significant effect on the growth of such tumours once they are established.

A recent contribution to the subject by Prudente¹ describes the use of testosterone as a post operative measure for the prevention of recurrence in human breast cancer. Sixty-three cases which had originally been subjected to radical amputation were subsequently treated with testosterone propionate in dosages ranging from 25 to 175 mg a week for prolonged periods. Of these, 24 cases had been observed for more than three years at the time of the report, 12 for more than four years, and 4 more than five years. Virilization during treatment occurred in 10, being severe in 5 and moderate in 3. A control group was provided by 64 comparable cases in which the breast had been removed by the same technique of radical surgery in an earlier period of seven years, but in which testosterone was not employed. All cases were confirmed microscopically, and classified first by a system based on both clinical and pathological criteria, and secondly in histological grades of malignancy. No case showed more distant spread than to the axillary nodes.

Apart from a good deal of speculation which has little direct bearing and can in no way affect the outcome of the experiment, the essential results are presented in a series of tables. Even if it be conceded that the data are consistent with the truth of Prudente's claim—that treatment with testosterone has produced a survival rate without recurrence twice as great as in the control series—closer study raises considerable doubt whether such is not in fact only one of a number of equally likely explanations. This is not to say that the investigation does not represent a substantial contribution of effort and no doubt careful observation, and the author himself is well aware that the series are not large and that other objections might be raised. But under the conditions of this present study, it is probably wise not to accept the data as constituting evidence sufficient to support a thesis which is far too important to be lightly accepted or lightly dismissed. Only the growth of experience on a larger scale and over a longer time, and under more adequately controlled conditions, can provide a conclusive answer.

RORSCHACH TEST AFTER HEAD INJURY

The Rorschach ink blot test occupies a unique position among psychological tests in that it can be, and is, used to test more than one function of the kind. From it the skilled interpreter can obtain indications of his subject's intelligence, power of imagination, and capacity for synthesis, and also of such emotional qualities as tendencies to hypochondriasis or depression, or schizophrenic traits. This great flexibility has to be paid for by an element of subjectivity and ambiguity, and the results of the test cannot be expressed very satisfactorily in a metrical form. It is therefore all the more interesting to see the test used, as it has been by Zangwill,² to explore the disturbances of function that occur after severe head injury. Two young men, both of good intelligence and normal personality, suffered from closed confusional injuries mainly incident on the frontal region, and were unconscious for three and for five days. They subsequently went into confusional states, without notable focal signs, which slowly cleared

They were given the Rorschach test during the night of the confusion, during the following hours of partial consciousness, and finally when improvement was complete and stable. These stages were accompanied by significant changes in Rorschach response. At the height of the confusion the cards were responded to as wholes and in one aspect—e.g., that of colour. There was great limitation of response, indicating a generalized limitation of cognitive activity. The bizarreness of the responses might be in part attributable to paraphasia, but in part also to a more general disturbance of thought and affect. In the Korsakow phase paraphasic and peculiar responses had abated, and there was now seen a tendency to project into the design reflections of dominant emotional preoccupations—in the one case conflict and aggression, in the other injury and mutilation. Zangwill believes that at this point the test can provide indications of the eventual direction of post-traumatic personality change.

PLANNING HOURS OF WORK IN AUSTRALIA

The hours of work problem during wartime troubled Australia as it did this country, and in October, 1942 the Governor-General, acting under the National Service Act of 1939-40, issued a series of regulations dealing with the subject. They have now been republished in a pamphlet entitled *Planning Hours of Work*,¹ which describes their practical application in some detail. The first part explains the effects of too long hours in reducing production, and indicates the best weekly hours for a sustained maximum output. The 48 hour week is taken as a standard, which may be increased to 56 hours for men and 52 hours for women, if engaged on light physical work. For men employed on heavy physical work they were limited to 44-46 hours but in emergencies the hours mentioned might be exceeded for short periods. Young persons under 18 years of age were specially protected, and it was recommended that they should not be asked to work regularly for more than 44 hours a week. If these regulations were strictly acted upon, they formed a more rigid and enlightened scheme than the irregular arrangements frequently followed in this country.

The latter half of the pamphlet gives detailed advice on the various ways in which the working hours may be most conveniently split up. Great stress is laid on the importance of allowing at least one day free from work every week, and a number of tables are given suggesting the best working periods to be adopted for a two-shift or three-shift system. The disadvantages of night work for women are emphasized, and it is stated that managers who had adopted it generally replaced it by two day shifts as soon as they could. Ten-minute rest pauses, for tea are recommended during all work spells. In a number of factories annual leave for a week, on a roster system was found to have a good effect in keeping up production. The Industrial Welfare Division of the Department of Labour and National Service of Australia, which has already issued a number of manuals, bulletins and leaflets dealing with industry, is to be congratulated on its latest addition.

¹ Bulletin No. 4 of Industrial Division of Department of Labour and National Service, Australia. Nichols Building, 37, Swinarton Street, Melbourne.

The House of Delegates of the American Medical Association has awarded the Distinguished Service Medal to Dr. George R. Minot for his great contribution to our knowledge of the causes of pernicious anaemia and the methods of controlling it.

A GENERAL SURGEON AT SEA

A REVIEW OF 700 CASES TREATED IN THE DOWNS

BY

JAMES S. HALL, M.B.Lond., F.R.C.S.Ed.
Surgeon, E.M.S., Deal

This is a story of an attempt to render urgent medical assistance to ships of all nations in the roads off Deal during the six years of war. I hope that a brief survey of the diversity of cases and the unusual setting may prove of some general interest and perhaps help my successor in the next world war, should he have to undertake the difficult task of dovetailing his general practice with emergency calls to sea.

The Downs have been a famous anchorage throughout our history, and comprise 50 sq. miles (130 sq. km.) of sea between the shingle beaches of Deal and Walmer and the Goodwin Sands. Julius Caesar is said to have anchored here for the first invasion of Britain, and in Nelson's day they frequently contained the entire British Fleet. During this war, when a carefully sown minefield blocked the outer reaches of the North Sea, the entire shipping traffic through the Channel was forced to pass through or anchor inside the Sands, which lie some five miles (8 km.) from the shore. A deep-water channel between these and the five-fathom (9 m.) bank two miles (3.2 km.) from the beach affords sufficient space and safety for several hundred vessels in almost any weather.

In Sept., 1939, a Naval Contraband Control closed both ends of the anchorage with guardships and subjected all vessels to rigorous search and detention, sometimes for many weeks. No communication between vessels themselves or the shore was permitted and all wireless transmitters were sealed. Contact was maintained by examination tugs and urgent need indicated by the hoisting of simple flag signals in the international code. In dense fog these were replaced by equivalent letters in Morse on the ship's siren. Under the general administration of the Dover Command the control work fell to the naval base at Ramsgate. It soon became evident that provisions, fuel, and urgent medical aid would have to be supplied from shore, and a fortnight after the outbreak of war I was asked to undertake the work of visiting surgeon. The local fishermen provided a rota of small motor-boats, and when weather conditions were such that no other vessels could be launched we were empowered to call out the Walmer lifeboat. At first the hardships of work at sea were overshadowed by the discomforts of strict naval discipline. An armed guard attended all visits to ships, and before visiting and after leaving each ship the small boats had to report to the guardship on duty. This wasted hours of useful time, as no boat had a speed of more than six knots and frequently had to travel several miles against a four-knot tide. Eventually I managed to obtain a free hand and, flying a Geneva flag as a protection from warning rounds from the guardships, we had free access to the ships and shore, with a general permission to take any necessary action to save life provided that our movements were immediately reported to H.M. Coastguard and later, in writing, to the naval officer in charge.

The work done covers two distinct periods. Up to June, 1940, we dealt with 298 cases in 130 ships, and then, with the fall of France and the installation of heavy cross-channel guns, anchorage became impossible, and even the small examination tug was driven back to her base by salvos of 16-inch shells and constant air attacks. Such convoys as were essential came through at high speed with balloon protection and a smoke screen, or perhaps under cover of the heavy morning mist. With the fall of Calais in Oct., 1944, a Control was re-established, and my work began again. During the next twelve months a further series of 404 patients were attended in 153 ships.

The incidence of nationality is interesting, as it gives a cross-section of the merchant navies serving our ports at the beginning and the end of the war. British ships, of course, form a high proportion at both times, although in a joint total American vessels hold the lead. In the first year the American flag was an unusual sight from the shore, and I visited only two of their ships, seeing three patients in all. The latter half of the work produced 88, mostly Liberty ships, with 209 patients. During the early years the Downs became a kaleidoscope of European flags, with the tricolour Dutch and the blue-and-white Greek

TABLE I.—Nationality of Ships and Patients

* Portuguese patient in American ship. † British Indian in Estonian ship.

forming the majority, and these two nations provided a large number of my urgent calls. At this time all neutral vessels had their national colours painted on their sides—a great help in our search for ships often crowded together or many miles apart. On occasion, however, when we had to find a case of attempted murder in an Estonian ship or treat two citizens from the Republic of Panama, we discovered that nobody in the boat had any idea of what the flags looked like. Language is a considerable problem, but usually the master speaks good English and somebody among the crew can be found to act as an interpreter. The main trouble arises on shore when operation cases are admitted to hospital and one finds a row of half a dozen patients all speaking different languages and no English. I always wondered how the nursing staff overcame this difficulty. In general, a smattering of French, German, and Italian is of considerable help; but there are many pitfalls, as I found when I took a nurse over a dark and stormy sea to give an enema to a Portuguese with acute constipation. It was not till next day that we found that *não bom* does not refer to a part of the anatomy, and *a constipação* means a severe cold in the head. But I still treasure a letter of grateful thanks from the owners for our successful treatment of the case. One interesting psychological fact shown by the tables is that while the northern European nations are too healthy or too proud to ask for treatment or advice for extra members of their crews, the remainder endeavour to obtain good value for their money by asking a visiting doctor to see every sick man on the ship. When a ship has just been mined or torpedoed and is in danger of breaking up it is curious how many of her company require urgent medical treatment ashore, and on Greek ships I have known a patient to produce and finger a long evil-looking knife when his symptoms were thought insufficient. On such occasions the discreet doctor will avoid the darker alley-ways when leaving the ship. Most of these cases occurred in the earlier part of the war when mines and enemy action were rife. Pure neurosis was rare, but I was once called to a ship to prevent two men being lynched by their fellows for spreading depression and alarm. There was none of this sort of thing in the second period.

At first the routine method of obtaining medical assistance was the hoisting of a "W" flag on the foremast or triatic stay. This flag, made up of concentric blue, white, and red squares, indicates urgent need of a doctor without specifying the cause. It proved a great help in finding the right ship, but one requires considerable foresight in packing a bag against any possible contingency. Distance and rough seas not infrequently make it impracticable to return ashore for missing kit. We were always able to launch from a shingle beach, but with a heavy swell it is sometimes necessary to lie off shore for an hour or more before a safe landing can be made. In fog the "W" signal is sounded in Morse on the ship's hooter (— —) for several minutes. Then one spends several hours trying to find where the hoot had come from. The worst type of call is a verbal message or radio signal giving the name of the vessel without any indication of position. In the later stages of the war all ships took to grey or black paint and the names appeared only on small removable wooden boards on the bridge, illegible a quarter of a mile away. Sometimes an Atlantic convoy would come in bearing none. In such a case

only a ship to ship call will yield results, but it may entail covering a zigzag course of twenty miles (32 km) or more. We always found the ship in the end if it was in the anchorage at all but once it took over ten hours from 3 p.m. till 1.30 a.m.—when we found the vessel completely blacked out off Broadstairs. On average our journeys lasted about three hours.

The list in Table II includes all cases seen on board in addition to the urgent condition initiating the message. Just under 300 patients were treated in the first period and just over 400 in the second. The large preponderance of injuries in 1939-40 is

chiefly due to enemy action during the evacuation from Dunkirk, which provided us with nearly continuous work, day and night, for the last fortnight in May, 1940. The large number of inoculations in the second period came from two Dutch steamers whose entire crew required typhus, cholera, and T.A.B. vaccine on board at short notice. Venereal disease is high in the scale and bearing in mind that mostly atypical cases occurred in the list is in actual fact even higher. Most American ships carry penicillin and all have sulphathiazole, with a purser well instructed in their use. I once found one sportsman having gonorrhoea for the eighth time, but he was only produced as a curiosity. These pursers are given several months' intensive medical instruction and after examination are awarded the diploma of a Pharmacist's Mate. Their diagnostic ability is high, several I met were advanced medical students, and it was a rare thing to find that any incorrect treatment was given. About two thirds of the V.D. cases were diplococcal or resistant streptococcal urethritis, and one third syphilis or chancre patients. A favourite method of giving penicillin was in 10,000 unit doses every three hours for thirty hours. Under this scheme, of course, neither the purser nor his patient got any sleep, and this probably accounted for the unpopularity of the patient above when he remarked that he was nearly ready for his ninth. The general efficiency in diagnosis and treatment is just as evident in all cases at sea, and is in distinct contrast with similar cases on land. Only once did I find burns treated with oil, and then by the patient himself. All the appendix cases were well starved, with purgatives withheld, except one returning from West Africa. A complete list of his diet included melons, pomegranates and lemons, and was followed by the laconic note, "Patient was then sick." Rheumatoid arthritis is an extremely rare complaint at sea, as is also gastro duodenal ulcer. Most of the cases listed as rheumatism were transient fibrositis. Skin disease, rare in the first period, was fairly common in the second, the majority of men complaining of tinea or scabies. The use of benzyl benzoate preparations is not yet widely known, although most medicine chests contain a bottle. It may be, of course, that European crews tolerate a good deal of skin irritation without

complaint, while it is generally resented by the Americans. The great increase in sinusitis and tonsillitis seen in 1944-5 is due to the high incidence of American patients who had four times the amount of ear nose and throat trouble seen in a comparable number of Europeans.

I note without comment that the average American ship maintains its living quarters about 10° higher than those of other nations, a temperature of 70° F. being not unusual. It was not uncommon when boarding Liberty ships in a snowstorm to meet members of the crew walking about the passages amid ships almost naked, while the average patient in his bunk had only a pair of drawers and a single sheet. Enteritis and cholangitis—all these terms are to be taken in their widest sense—are common throughout, and occurred mostly in small vessels and British ships, which had few refrigerators. In the last few months of the war we found a few mild outbreaks of Sonne dysentery, and it is quite possible that several cases of paratyphoid were overlooked. Dental cases are frequent in American ships and it pays when answering a call to a case of suspected mumps, to carry a few dental forceps in the pocket. In the early days I brought cases ashore to a dental friend, but later an acute shortage of these useful gentlemen made it necessary to do extractions myself, and I found that most teeth can be removed with a straight incisor forceps while a whiff of chloroform makes the job more comfortable for everybody concerned. It also proved satisfactory for minor operation cases where local analgesia was impracticable. Most of these are better done ashore if weather conditions permit the transfer of the patient to a small boat. If not the operator is advised to sit astride the patient and move with him, this produces relative stability. In all I did 29 operations on board, all minor cases. Before starting it is as well to see that mine sweepers are not working in the vicinity, especially if you are removing cysts or foreign bodies from the eye or lids. A magnetic mine exploding a hundred yards away will throw a patient out of his bunk. One unlucky Finn I attended with a renal calculus had eleven such mines round his ship, but still refused to come ashore. This condition is always diagnosed accurately on board ship and in no case could I disprove it by x-ray examination ashore. Once, indeed the captain of a Dutch tramp had explained the probable operation so well in High Dutch to his chief engineer that I was able to land him and perform a nephrolithotomy without delay or argument.

Table III shows the suspected emergencies on board 262 ships and is derived from the actual messages received or the opinion stated by the ship's officer in charge of the patient—on American ships the purser on the rest the master, the mate

or the steward. A careful perusal of these will almost answer the question, "What should the doctor put in the little black bag?" I was lucky enough to have three large gladstone bags with linings fitted for instruments, and these just lasted out the war. Sea-water, and the battering against ships' sides as the

bag is pulled up with a heaving-line, demand good leather and careful packing. A set of surgical instruments and suture material are essential, and are best contained in a stout spirit-proof case. Water on a ship is never sterile, and it saves time to arrive with everything already aseptic. Soft-tissue injuries formed the highest quota of urgent calls—nearly 15% of the total. With fractures, dislocations, and burns added, one is likely to find some form of trauma in more than 25% of cases.

Suspected appendicitis is the largest bogey facing the unqualified ship doctor. Out of 31 such patients I found 15 genuine cases, operated on—8, resolved 2 with penicillin—one a boy, of 17 who had perforated in mid-Atlantic six days before, and came ashore almost moribund with peritonitis and paralytic ileus; the other a Chinese who refused operation after his appendix perforated during his journey in, with temporary relief of pain. ("No makee cut; me velly better.") We had to use our last 100,000 units on him. The others settled down with medical treatment and left hospital promising to undergo interval appendicectomy elsewhere. The 16 other cases had either acute abdominal pain from gall-stone, or intestinal colic, acute enteritis, or some form of right-sided discomfort. These include an inguinal bubo, saphenous phlebitis, two hernias, several cases of acute orchitis, and a hydrocele. Two pleuritis and a fibrositis made up the medical contribution. Another great bogey is suspected infectious disease. I have listed only genuine cases, which include all the common exanthemata. We were extremely lucky to avoid smallpox, cholera, and typhus. All were left on board in isolation, and it is prudent to take anti-scarlet-fever and anti-diphtheria sera in the bag so that no reproach can lie on this score when one advises that the patient should remain in his bunk. In at least as many cases again, suspicion of infection may have been a serious factor. One Dutch captain thought he had acute phthisis when he developed pain and haemoptysis, but examination showed intercostal shingles, which cleared up rapidly with aneurin injections and radiant heat. In his case the infection appeared to have come from two pots of raspberry jam sent to him by an old lady in Holland who regretted that she had had to curtail her usual half-dozen owing to shingles. At any rate, he and his crew had been away from any kind of contact with shore for over six weeks.

Venereal disease is a problem, and forms 10% of emergencies. Most ships carry sulphathiazole and treat gonorrhoea with a course of 50 to 60 g. (1 g. 4-hourly). This clears up most of the cases, but does not improve the frequent non-specific posterior urethritis, which hangs on for weeks. I put these people on large doses of hexamine and advised them to seek out a genito-urinary surgeon in the next port. Soft chancre and various stages of treated and untreated syphilis were only too common. It proved useful to carry a bismuth suspension and a first-and-last dose of N.A.B., as in most cases it was essential to provide adequate interim treatment till the ship reached port, probably in less than a week. Only American vessels carry penicillin, which simplifies treatment; and in these my opinion was chiefly sought about the risk of infection. At least three cases occurred among ships' cooks, and many among the armed guard, who live in rather close personal contact.

Ischio-rectal abscesses were common among the septic conditions, and a nice judgment is required as to whether to risk incision on board. In all cases I found them ripe underneath, and earned a good deal of temporary gratitude. Most of the remainder were pointing somewhere or other by the time we were called, and I had the impression that the general resistance to infection was much higher among seamen than in my patients on shore.

I think that all the heart cases treated on board occurred in elderly ships' captains, and all appeared to be due to gross overstrain and lack of sleep. The last was that of a pilot who collapsed on the bridge after giving a compass bearing which would have piled the ship up on the Goodwins. Fortunately the skipper, standing by, saw the breakers ahead and reversed the order. This unfortunate man had had no sleep for four days and no holiday for a year.

Foreign bodies in the eye seem much more common than the statistics show, and a little 5% cocaine and an eye spud more than earn their keep. I found a tube of mercuriolate and metyrcain a useful remedy for most ophthalmic cases. It is probably

too dangerous to leave atropine with no supervision for several days.

Five bodies were brought ashore. Although the ships concerned were more than three miles (4.8 km.) from the beach, inquests took place on two cases of accidental death and a suicide—that of a Belgian who hanged himself. When one has knowledge of these fatalities—as when a British ship hoisted the three-flag signal "E.N.L." (Death)—it saves a lot of time to invite the coroner's officer to take a sea trip. If he doesn't like boating there is certain to be a deputy who does.

Serious cases needing treatment ashore were all brought in by small boat and a deep wire stretcher with blankets; a pillow is always put in unless we know that it will not be required. After trying out almost every method I believe the safest way to get a stretcher case from a ship into a small boat is to lower it down the side with four separate ropes and a man holding each, with a boatswain in general charge so that when the receiving party in the boat have a firm hold the ropes are dropped completely slack. A good alternative is the same system with four cleats and a derrick slung well out, or a boatswain's chair for a sitting case. We landed 146 cases, and I do not think any were the worse for the journey, though sometimes our little boats were half full of snow.

In all, 114 cases were admitted to the Victoria Hospital, Deal, and I cannot too highly evaluate the devoted nursing these received and the remarkable way in which the sisters in charge overcame the language difficulties. Apart from four moribund patients who died from heart failure within 48 hours of landing, we had only one fatality in the first series. This was one of five cooks in the R.M.S. *Dunbar Castle*, one of the first ships to be sunk by a magnetic mine in the Thames Estuary. These unfortunate men were frying fish on a form of primus stove in the depths of the liner when her bottom was blown out. All five had third-degree burns of the face, hands, and arms from the boiling fat and burning Diesel oil when the mine exploded. All made a good recovery except one man whose face and both eyes were completely destroyed. He developed a rapidly fatal septic meningitis on the third day.

There were no fatal cases in the second period, and all the patients left hospital in a satisfactory condition after treatment. In several cases of appendicectomy and a strangulated hernia we were able to send the patients back to the ships on their return to the anchorage ten days later, much to the satisfaction of everybody concerned. As all this immigration was entirely unorthodox I was personally responsible for all patients brought ashore till they had been vetted by the Security Police from Folkestone or Dover. To avoid difficulties I admitted all cases to my own beds and, so far as was possible, dealt with them myself. I have to thank my partner, Dr. C. B. Hutchison, who gave all the anaesthetics, and Dr. C. P. F. Boulden for their unstinting help with the medical cases and pathology; and all my colleagues for their assistance and support. Dr. D. W. Kirk, M.O.H. for Deal, arranged accommodation for shipwrecked personnel and put his civil defence organization at our disposal for casualties. The St. John Ambulance Brigade drivers turned out at all hours in response to my light signals from ships, and the ambulance was always waiting when we grounded on the beach.

Throughout the entire war the work was made possible only by the unflinching help and courtesy received from the naval authorities at Dover and Ramsgate and the untiring co-operation of H.M. Coastguard at Deal. I have an eternal respect for the Deal boatmen who took me out in all weather conditions, often risking their boats and their lives to get me safely aboard; and especially for Messrs. J. Mercer and F. Upton, coxswains of the Walmer lifeboat, who took me out seventeen times when no other vessel could be launched. The Royal National Lifeboat Institution has given me every help, and I have a special word of thanks for a personal permission to use their electric capstan. But not for their rum ration, carried on all lifeboats, which in all the six years of war I have not yet been able to broach.

Summary

An account of an emergency casualty service to shipping off the south-east coast is given, with some description of the organization found necessary and three tables showing the incidence of diseases and nationality. In all, 702 cases were dealt with—556 on board

Reports of Societies

CHRONIC CHOLECYSTITIS

At a combined meeting of the Sections of Medicine and Surgery of the Royal Society of Medicine on Jan. 29, with Dr. T. Izod BENNETT presiding, a discussion was held on the diagnosis and treatment of chronic cholecystitis.

Dr. MAURICE SHAW said that not much was known about the milder degrees of cholecystitis. He had been accustomed to regard the condition as divisible into two types—an interstitial infection and a catarrhal infection, in which latter the mucous membrane of the gall-bladder was affected but functioning was reasonably good. One question was why extreme flatulence should be associated with the condition. It was usually supposed that gastric flatulence was entirely due to swallowed air, and experience did not suggest that patients with gall-stones were more likely than others to be air-swallowers. His own feeling was that the explanation of the flatulence was not the swallowed air but the increased reflex tension of the stomach, which was relieved by bringing up excessive air.

The mainstay in the diagnosis of cholecystitis was radiology, but it was impossible for the radiologist to say whether the gall-bladder was normal or not, and if his supposition was correct that many of these patients were suffering from a catarrhal condition of the mucous membrane it seemed unlikely that radiology would be able to detect it. Gall-bladders which were radiologically normal, filling and emptying within normal limits, might nevertheless be abnormal. A frequent instance was the patient with symptoms suggestive of gall-bladder disease, with physical signs, but in whom the radiologist could find nothing really abnormal, beyond possibly a slight defect in emptying or filling. Where there were gross radiological abnormalities all would agree that operative surgery was needed. Another indication for surgery was complete failure of medical treatment. A patient with convincing clinical evidence of gall-bladder disease who failed to respond to medical treatment must have surgical treatment, even though, as often happened, the surgeon was reluctant to operate because he had not got all the evidence he wanted.

The type of chronic cholecystitis most amenable to medical treatment was the catarrhal type. Dr. Shaw had never seen any sound reason for placing a patient with gall-bladder disease on a fat-free diet. The idea was based on a misconception as to the role of cholesterol. In diabetes, where there was likely to be a high cholesterol content of the bile, there was no marked tendency to the formation of gall-stones. The argument for withholding fat for fear of increasing the cholesterol content of the bile seemed to break down, and the only other argument for excluding fat from the diet was that many patients thought they could not take it. Usually, however, it was only certain kinds of fat to which they were averse, particularly fried fat, which had a hard envelope. Fats such as butter, eggs, and cream were well tolerated. If the object was drainage of the gall-bladder by non-surgical methods fats were most valuable, and he saw no objection to feeding patients on a high fat diet in the effort to make the gall-bladder contract and empty the bile. Fats should be restricted only when they caused discomfort. Other methods of drainage were often used. Magnesium sulphate had a great reputation, although the actual evidence that it caused contraction of the gall-bladder was not entirely satisfactory. The use of the duodenal tube in this country was not widespread, because it was generally felt that the same result could be obtained by giving drugs by the mouth. Of the drugs most widely used for disinfection—the salicylates, the hexamines, and the sulphonamides—he had had a certain amount of success with hexamine but he was not very enthusiastic. It had to be used in large doses and with caution. Sulphonamides had been successfully used and had been shown to have significant concentrations in the bile.

Radiographic Indications

Dr. G. CALTHROP said that cholecystitis was a disease of the walls of the gall-bladder, and, the gall-bladder and the bile being made up of chemical elements similar to those of the surrounding tissues, x rays did not differentiate them. It had been said that the gall-bladder could be seen in plain films.

However that might be, whenever he had identified the gall-bladder in the preliminary radiograph, the cholecystographs later on showed it to be in an entirely different place. When the gall-stone contained calcium or when the walls of the gall-bladder were calcified a shadow was produced on the film, just as it was by a barium meal. The same thing happened in cholecystography, which was an adaptation of Rowntree and Abel's discovery that phthalein was extracted from the blood by the liver and excreted in the bile. Recently an entirely new contrast medium, pheniodol B.P., had been produced, disturbing the patient less than the phthalein compounds.

When the gall-bladder failed to fill with and to concentrate the opaque medium four things might have happened: the medium might never have been extracted from the blood; or, like the bile, it might never have been able to leave the liver or to reach the common bile duct; or the iodine content of the bile might have been prevented from reaching the gall-bladder by a calculus, adhesions, or other cause; or, finally, the mucous membrane of the gall-bladder might have lost its power to concentrate the bile, whether gall-stones were present or not (true cholecystitis).

He went on to point out some fallacies. Putting aside congenital abnormalities, a gall-bladder might not be visualized because, so to speak, it was no longer there. Not infrequently cholecystography was requested after cholecystectomy. Improper preparation and poor radiographic technique, such as wrong dosage of opaque medium, movement during exposure, incorrect positioning, and other factors, could and did often mislead.

To sum up, the gall-bladder might be radiologically normal in appearance and function and yet there might be a pathological condition, but if a proper technique had been used and the gall-bladder failed to fill with and to concentrate the opaque medium a pathological condition was practically always present, not necessarily in the gall-bladder or its duct, but usually so. Since radiologically it was not possible to see whether a disease was outside the gall-bladder, due to one or more non-opaque gall-stones or to cholecystitis, there was obviously no direct radiological sign of cholecystitis. When there was only a poor filling and no gall-stones could be seen, care was needed and clinical evidence must be very definite, otherwise it was better to check by a second examination after an interval.

Chronic Cholecystitis without Stone

Mr. A. J. GARDHAM said that cases with a presumptive diagnosis of chronic cholecystitis without stone might be divided into two groups: (1) those in which disease of the biliary system was indicated by the presence of jaundice; and (2) those in which such disease had been diagnosed on less certain grounds. The picture in the latter group as he encountered it was fairly typical. The patient was generally a woman, often of the type or habit traditionally associated with gall-stones, and complained of pain in the right upper abdomen, though never of the severity of a true biliary colic. If the gall-bladder failed to show altogether on cholecystography he generally took it that he was dealing with a cystic duct which was blocked by a stone not opaque to x rays. If he was assured of the technical efficiency of the x-ray examination he was prepared to accept the evidence that there was no shadow on cholecystography as meaning that a stone was present. In doing so he was taking a risk of being deceived, but he thought the risk was small, for no one would quarrel with the removal of an organ obviously diseased, whether stones were present or not.

The group of cases in which function was shown on x-ray examination to be unimpaired or only diminished made a different story. The only justification for operation in cases of that kind was that a timely operation for the removal of a gall-bladder not yet grossly diseased might prevent the formation of gall-stones and the invalidism which resulted from the presence of stones in patients who were no longer in a fit condition to stand the operation of cholecystectomy. His impression was that the patients who suffered from the symptoms generally attributed to cholecystitis without stones were of a younger age group than those who came up with cholelithiasis. If active steps were taken in these cases there would be fewer old people bound to endure the symptoms which resulted from stone without being fit to undergo the major operation. If the theory of infection as a primary cause of gall-stones was

it unnecessary to assume that the original sepsis had anything more than a small share in the deafness—in other words, the man should be given the benefit of the doubt.

Noise or gunfire deafness produced a most easily recognizable clinical picture. There might be little or no involvement of the lower frequencies but a very severe loss in the higher. When cases of concussion deafness, of the middle-ear type, were seen, usually long after the injury, it might be impossible to tell to what extent the structure had been involved in the original damage. In the majority of cases the astonishing thing was the correlation between the resulting deafness and the severity of the original cranial injury, contrasting markedly with other cases in which a slight blow on the head, without bone damage or even a scalp wound, might result in severe middle-ear deafness. He added that the Ministry of Pensions was not engaged in original research, and it could not wait until its decisions were based on incontestable facts. Decisions had to be made promptly and with as little risk as possible of injury to the men concerned. Where there was a doubt the benefit of it was given to them.

Rehabilitation

Air Cdre. E. D. D. DICKSON said that deafened Service personnel fell into three categories: (1) those who had some hearing loss before joining and whose defect passed unnoticed; (2) those with some hearing defect which progressively became worse in service; and (3) those whose disability was attributable to service. It was considered to be the responsibility of the Ministry of Pensions to organize schemes of rehabilitation, particularly for those whose disability was due to, or increased by, their service. The Ministry of Pensions would prefer treatment within the Service; postponement until after the patients were discharged made the co-ordination of different forms of treatment impracticable. All deafened and hard-of-hearing patients needed instruction in lip-reading. Patients invalided from the Service on account of deafness should be posted to a rehabilitation centre, where assessment could be made. The speaker outlined the functions and personnel of such a centre, where instruction could be given in classes and facilities for occupational therapy installed on a comprehensive scale.

The PRESIDENT recalled that in the first world war men were recruited without sufficient preliminary examination, and apparently the mistake had been made again. During that first war he had care of a very large number of cases of middle-ear suppuration in hospital and was struck by the good results obtained by routine measures. He hoped that pressure would be brought to bear on the Ministries concerned so that within the next few weeks or months something would be organized for the rehabilitation of these unfortunate people.

Mr. R. G. MACBETH gave his impressions of a recent visit to the Naval Hospital, Philadelphia, which was devoted largely to rehabilitation. A deafened Service man was sent back to his depot, and after a period of leave was directed to the hospital, where he was carefully examined by skilled otologists, and if there was any physical disease, whether attributable to war or not, he was assessed from the point of view of his hearing. If necessary he was given lip-reading instruction. He was placed in a ward with other people suffering from various disabilities, not hearing disabilities alone, and therefore he had less occasion for feeling very sorry for himself, and morale was kept at a high level. Each morning the men received instruction and undertook certain duties, but the rest of the day was free for them to do as they wished, within the framework of a naval organization, and he had seen these deafened men enjoying concerts. They were obviously on the way to becoming useful citizens.

Testing Out the Malingeringer

Mr. T. B. LAYTON said that complete deafness in one ear, with the other ear normal, was not such a grave disability as a smaller degree of bilateral deafness, because the individual could compensate by positioning and movements of the head. Many deafened people were able to carry on a conversation with another individual across the table, but were quite unable to follow the conversation of a number of people and therefore were at a disadvantage in social life and in wage-earning capacity. In making tests there were three physiological reactions which should be assessed: the time-lag of the individual, the definiteness of his response, and his power of switching from one subject to another. Auditory attention was both

conscious and subconscious. When conscious attention was in opposition to the examiner the person under test was a malingeringer, but there were a far larger number of cases in which there was subconscious inattention—the conscious attention was directed to the examiner, but the subconscious was withdrawn. It was always a question of how far this was due to ear defect. He believed that when a person had for a long time been deaf the subconscious attention tended to atrophy. No one should be written down as a malingeringer until tests had been performed so thoroughly that the evidence would not break down under cross-examination, supposing the case came into court, as it never did. In such cases as he had described he felt that there was something pathologically wrong with the attention, that it had been damaged either by disease or by external causes, and such persons should be given credit for their disability in the same way as for structural deafness.

Mr. F. C. ORMEROD said that the Ministry of Pensions was much more sympathetic now than after the last war, when it was difficult to persuade the Ministry that many of these cases were aggravated by war service. Mr. R. SCOTT STEVENSON said that a man with chronic middle-ear suppuration but good hearing did not get a pension, yet no otologist would pass such a man for life assurance. Mr. C. HAMBLIN-THOMAS spoke of the difficulty of getting trained technicians to carry out treatment. Out-patient treatment was not as satisfactory as treatment in hospital. Mr. MICHAEL VLASTO said that he was probably the only otologist present who did not use the audiometer. All his work was based on the history of the patient and tuning-fork and voice tests. He did not find that from the patient's point of view he had had any real assistance from audiometric readings. Mr. I. G. ROBIN mentioned the case of a medical man who was so deaf on leaving the Service that he had to give up any thought of returning to his practice; yet he got only 50% disability and was awarded a lump sum of £50. Dr. SIMSON HALL asked whether there had been any research on the causation of nerve deafness—by bone conduction—for example, the use of sponge rubber heels to avoid transmitting concussion. Mr. C. P. WILSON stressed the need for teaching not only the patient but his family, who could do a great deal to ameliorate the difficulties arising from fatigue and disturbing noises.

The PRESIDENT, following up Mr. Vlasto's remark, said that during the last two years he had relied entirely on tuning forks because he had not been able to get his audiometer serviced. Until the servicing of these instruments was placed on a better basis their utility would be much reduced.

Nova et Vetera

CARDIAC FOLK-LORE

At a recent meeting of the Section of the History of Medicine of the Royal Society of Medicine Dr. J. D. Rolleston said that it was generally agreed that a scientific study of heart disease did not begin until the seventeenth century. It was not surprising, therefore, that a vast amount of cardiac folk-lore developed and persisted for several centuries. Though the doctrine that lesions of the heart were generally fatal had been wrongly attributed to Hippocrates, it was undoubtedly of great antiquity. There was hardly a trace in classical literature of the severe cardiac diseases which subsequently played such an important part in scientific medicine, and the chief cardiac affections before the beginning of the nineteenth century were merely palpitation and pain in the cardiac region. Parrot had remarked that this ignorance of heart disease in antiquity might seem strange in view of the fact that other affections of less importance were thoroughly studied in ancient times, and suggested that the only explanation of this omission was that the heart was regarded as a sacred organ which it was wrong to touch or study. Even in the time of Erasistratus and Asclepiades knowledge of the heart was so vague that the same Greek word was applied to both heart and stomach, which was doubtless due to the juxtaposition of the two organs separated only by the diaphragm.

Dr. Rolleston said that the folk-lore treatment of heart disease might be considered under general measures, animal cures including coprotherapy, plant remedies, hydrotherapy, metals, and intercession by patron saints. It was noteworthy that in striking contrast with the great majority of diseases the patron saints invoked for the relief or cure were very few in number. Not only had numerous popular remedies been used in the treatment of cardiac disease, but in many instances the heart itself in man and animals as well as heart-shaped animals had been credited with prophylactic and curative properties.

Correspondence

Lay versus Medical Administration

SIR—Among the vast mass of letters, speeches, discussions etc. which I have either read or heard in connexion with the proposed national health scheme, I do not recollect any particular reference being made to the very important question of administration by which I mean is the chief officer of the administrative unit—regional, divisional or whatever it may be—to be a layman or medical man?

We may be quite certain that the chief administrative officer at the Ministry of Health will be as hitherto the Parliamentary Secretary, but what about the regional or other administrative body which is to deal with the work of the unit areas which we understand are to be set up throughout England and Wales? These units will presumably be groups of counties and county boroughs and their membership constituted by representatives of local authorities, voluntary hospitals and probably nominees of the Minister of Health. Such administrative units will require a staff organization to carry out the duties, responsibilities, and instructions of the joint council of the unit area. It is certain that the staff organization of each area will be considerable in numbers, will consist of both medical men and laymen and that, as the expert advisers of the joint council upon numerous problems of policy and practice, they will inevitably play an extremely important part in promoting the harmonious co-operation of the various interests represented in the joint council itself and the area or region with which it is concerned.

Judging this difficult and delicate problem from my own personal experience, I hope and pray that the Minister of Health will be persuaded and advised to appoint medical men as the chief administrative officers of these regional organizations inasmuch as the problems to be dealt with are, and will always be, predominantly medical, and will require above all other considerations the whole-hearted co-operation of the medical profession of the regional area. The danger I visualize is the appointment of such persons as the clerks of local authorities as chief administrative officers and if this is done, then, judging again from my own experience, Heaven help us—I am, etc.

London W 8

FREDERICK MENZIES

Physical Therapy in Mental Disorder

SIR—Although I am not a psychiatrist I should like to say how cordially I agree with Dr T H B Gladstone (Feb 2 p 179) in his condemnation of the bullying of relatives to gain their permission for ECT and leucotomy. I have seen this and also what appeared to me to be the indiscriminate use of electric convulsions and the light-hearted plotting of leucotomy. What successes these methods achieve are bitterly paid for by all the patients with the pain of cutting or pummeling with fear and dread hours, the imponderables of intense unhappiness I have heard "cardiazol" used as a threat for bad behaviour, the curative and the punitive merging.

Particularly do I find Dr Jan Frank's humour a little nauseating, for in an article by him in *Proceedings of the Royal Society of Medicine* in May last year (1945 38 317) he made it abundantly clear that the patients about whom he was writing had an intense hatred of these methods, though he seemed to view their antipathy with considerable detachment. Perhaps he has not been long enough away from Hitlerite Germany to appreciate our island prejudices against trying to do good by force against encroaching on the liberty even of the insane any more than is necessary, and against the experimental usage of Continental medicine. I do not doubt the sincerity and humanity of these shock tacticians or of those whom he is pleased to call "brain slashers" nor do I doubt the earnestness of many of the Spanish Inquisitors who thought the immortal soul was well worth a little flame and pain. My tradesman's view is that the soul and sanity may be too dearly bought. At present, so far as I can see, an A.M.O. in a mental hospital, having obtained the permission of the nearest relative by the exhibition of fact or frown or fancy, can then proceed

to sentence any patient to have his brain cut or to undergo a series of fits with no appeal. It is high time the Board of Control remembered their duty—the protection of patients in mental hospitals which are no longer as hazy from vision—I am, etc.

C G LEACOCK

Problem Families

SIR—Dr S W Savare in his paper on "Infant and Infant Mortality in Problem Families" (Jan 19 p 86) attempts to draw certain conclusions which are hinted at in the presentation of the figures. He comments for example on the fact that in the families with mothers of average intelligence over 50% of children were retarded two or more years in the problem families, but under 7% of children in the control families. This would appear to imply that retardation is brought about mainly by neglect of one sort or another and not by the inheritance of poor mentality as is commonly supposed. To render the issue more scientific, Dr Savare would agree the assessment of the children in terms of intellectual as well as scholastic retardation would be necessary. The two generally speaking, tend to run together but in the children of problem families the intellectual capacity (which is gauged by individual testing) might be higher than the educational achievement would lead one to suppose—owing to poor nutrition, lack of rest, loss of school time and other factors of neglect which might lower the latter. Also the intelligence of the fathers would need to be measured if the factor of heredity were to be fully considered. Within its limits however the investigation was well worth doing and it is a valuable commentary on a very practical and debated issue—I am, etc.

Birmingham

CHARLES BURN

Mesenteric Lymphadenitis

SIR—In Dr B O C Pridmore's letter (Jan 26 p 144) in support of his view that with regard to treatment he advocates laparotomy believing that a certain diagnosis of the condition can be made only when the appendix has already been removed. I wholeheartedly support this advice, and while Mr Aird's excellent article (Nov 17, 1945 p 680) has greatly clarified our views on enlarged mesenteric glands I would still be very hesitant to withhold surgery in cases of what would appear to be doubtful acute appendicitis particularly in children.

I have had occasion more than once to regret not having opened the abdomen for appendicitis but never for having removed an apparently normal appendix. Reflecting over one's cases of right-sided abdominal pain with fever and tenderness in the right iliac fossa during the past few years I find that while my diagnosis of appendicitis has in most instances been correct, I have removed a good many mildly inflamed or surgically normal appendices. The ultimate cause of the abdominal upset in these cases has often turned out to be a mild infection, jaundice, mild dysentery, or nothing more than enlarged mesenteric glands. All the patients have recovered without much anxiety, and in my opinion definitely appeared to benefit by the removal of the appendix, particularly so if mesenteric glands were present. To find the mesentery packed with pink white glands not unlike oversized boiled sago grains has become rather the rule than the exception in my practice of late years. I do not remember seeing them so frequently before the war and I have no explanation to offer for their more frequent occurrence now.

If we agree that one of the commonest causes of abdominal pain in childhood or the young adult is appendicitis I feel that it should be kept foremost in our minds and the appendix removed if there is the least doubt—I am, etc.

Aylesbury

RALPH H GARDNER

Abacterial Pyuria

SIR—I have read with great interest Dr David Peters' article on bacterial pyuria (Feb 2, p 160). It is gratifying to learn that my original communication first brought the condition to his notice. That paper, which, so far as I am aware, was the first publication on the subject in this country, I have frequently been informed has similarly been the means of making curative

therapy available for many sufferers from the disease. In one instance a surgeon read the article only just in time to prevent him from doing a nephrectomy for supposed tuberculosis. Dr. Peters has not apparently had the opportunity of reading a later but more complete publication of mine on "Sterile Pyuria, with Special Reference to True Infective Abacterial Pyuria" (*J. Urol.*, 1943, 49, 203). The points he raises on the aetiology of the disease are mostly dealt with there. Syphilis is not a factor and the Wassermann test is negative in these cases. Nor is there any relationship between the disease and Hunner's ulcer. Actually in most cases of the former disease there is no or only very slight pyuria. However, some cases of true infective abacterial pyuria do simulate the syndrome of "Simple Ulcers of the Bladder" described by Fenwick in 1896 (*Brit. med. J.*, 1, 1133). One of my earlier cases fell into this category, but this is a quite different condition from Hunner's ulcer.

I was also interested in Mr. Hugh Donovan's paper (July 7, 1945, p. 12) on abacterial pyuria; especially the presence of urethral discharge which he had observed in some of his cases. Personally I have not encountered this. Dr. Lydon, in a later issue of the *Journal* (Aug. 4, 1945, p. 167), wrote of the good result he had obtained in cases of urethritis, in which no organisms could be demonstrated in the discharge, by treatment with intravenous N.A.B. It has been my experience that, although such cases do gradually clear up with this treatment, the response is in no way so dramatic or so immediately related to the treatment as that in cases of true infective abacterial pyuria. I very much doubt if there is any relationship between the two conditions.

During my five years of service with the Forces I encountered several cases of true infective abacterial pyuria. Strangely enough one of the first I treated in North Africa in 1942 was just such a case, which had been evacuated to us as one of urinary tuberculosis. By curious coincidence I met the patient at a demobilization centre recently and was interested to learn that he had had no further urinary trouble.—I am, etc.,

Manchester.

THOMAS MOORE.

Cardiac Massage

SIR,—I would support Mr. Hamilton Bailey (Jan. 5, p. 29) and Prof. John Morley (Feb. 2, p. 177) in stressing the need for promptness in cardiac massage. Many of us are reluctant to make the incision for it, and stand by, hoping it will be unnecessary, while the life-saving minutes slip by for ever. The indication which I use for action is: "Is the heart beating or not?" It is a simple question, and it is for the surgeon to answer it and not for the anaesthetist, because the decision to massage the heart rests with him and also the job of doing it.

How is the answer to be obtained for certain? The anaesthetist cannot tell from the pulse. He often feels his own pulse in the anxiety of managing the collapsed patient. The remedy is for the surgeon to put his ear on to the patient's chest wall over the heart; the evidence is instantly available. On several occasions I have been able to reassure the worried anaesthetist that the heart was all right, and at other times I have heard nothing, and that silence has fired me into immediate cardiac massage with consistent success. Cardiac silence for 30 seconds means immediate heart massage. With regard to the duration of the massage, I keep on until both hands are tired, at least 5 to 10 minutes. On two occasions I have had the pleasure of the heart restarting and continuing when I was at the point of giving up through digital fatigue.

The guide, therefore, for any case of a failed heart is to put the ear to the chest wall instantly, and if "silence," massage steadily until the heart begins.—I am, etc.,

London, W. 1.

HAROLD DODD.

Anaesthesia

SIR,—Fashions change in every walk of life. They change in medicine too, and one wonders if they always do so for the best. I refer to anaesthesia. Twenty years ago, when I was a student, hundreds of thousands of successful anaesthetics were given with (a) open ether, or (b) the very simple Boyle's apparatus. Then came, in the early 1930's, (c) the godsend of barbiturate premedication, and anaesthesia, still maintaining its simplicity, stood high.

It still does, but it has got itself wrapped up with a mystic halo of Heath-Robinson mumbo-jumbo, which the average humble general practitioner anaesthetist finds somewhat overpowering. Students and housemen are nurtured on giant contraptions worth hundreds of pounds—and cannot give open chloroform. I am told that avertin is going out of fashion because the pundits say that the dose depends not on the weight of a patient but on the metabolism. A small series of 400 cases, ranging from 7 months to 79 years of age, has convinced me of the great value of avertin, which no academic utterance will change. While appreciating and acknowledging the fact that the specialist anaesthetist is necessary in many of the rare and specialized operations, let us not be "kidded" into the impression that this simple branch of medicine is a mysterious cult known only to the favoured few. Let it be hoped that it will not become more over-specialized than it is now, and that the advent of the "premedicationist," the "pentothalist," and the "open etherist" will be long delayed. I do not think that modern anaesthesia, with all its trappings, tubes, taps, and turncocks, is any great improvement on the older methods, and the fact that anaesthetic deaths have not decreased appreciably from the tiny percentage of fifteen years ago may substantiate this. I now, Sir, bow my devoted head and wait for the storm to burst.—I am, etc.,

Aylesbury, Bucks.

W. A. BELLAMY.

Responsibility for the Anaesthetic

SIR,—Mr. Lyall certainly "puts the cat among the pigeons" in his letter (Jan. 26, p. 144), and like a dutiful pigeon I rise to join in the required commotion. His suggestion that the choice of anaesthetic is a matter for the surgeon rather than the anaesthetist is belied in his own first paragraph, where he suggests that "respiratory trouble" is an indication for spinal analgesia. I think most anaesthetists will agree with me that this is a contraindication to spinal, since the primary requirement in "chesty" cases is to be able to sit them up in Fowler's position immediately after operation. Cyclopropane is the anaesthetic of choice in these cases, or, if that is not available, gas, oxygen, and ether with CO₂ absorption.

It is just such misconceptions as this which make us claim that the anaesthetist should always have the last word. The surgeon should state his requirements within the operation field—duration, degree of relaxation, etc.—and the method by which these requirements are met is entirely an anaesthetic matter and should be decided by the specialist in that subject. In actual practice, in experience with many different surgeons, I have never had anything but complete co-operation over this matter. The tone of Mr. Lyall's letter suggests that he has been less fortunate in his association with "professional anaesthetists." But if this is so, I believe his experience to be the exception rather than the rule.—I am, etc.,

B.A.O.R.

PETER S. CHESHIRE,
Fl. Lieut., R.A.F.V.R.

Spinal Analgesia

SIR,—I am still more surprised and perplexed as to why Mr. Lyall (Jan. 26, p. 144) does not use spinal in his appendicitis cases, for the reasons I have given; yet he "invariably" uses this method in resection of the colon, when the patients are older and usually more toxic, less resilient, less able to stand shock, and where a higher level of analgesia is required. As regards "quick" appendix operations, they are very rarely necessary and would be usually very inadvisable indeed. Even so, the spinal is quicker to give, makes the operation quicker to perform, for the reasons I gave, and recovery is as speedy as, if not speedier than, recovery from ether and very much more pleasant. To me it is very satisfying indeed to take the blind off the patient's eyes immediately the last stitch is in and say: "How are you?" and to get the answer: "Very well, sir; is it all over? Thanks very much." This is anaesthesia *par excellence*, and I contend that Mr. Lyall might have attained this with the utmost safety in the great majority of his most interesting series.

Surely spinal analgesia is a most rational method for, at least, all lower abdominal and pelvic surgery. Why saturate

a patient's brain with an inhalation of poisonous vapours and gases or by an intravenous injection of drugs causing complete unconsciousness, which, in itself, puts the patient in the region between life and death and on the way to the latter? The spinal, which desensitizes the lower half of the spinal cord and which can now be safely controlled, is all that is necessary, and is only an extension of local and regional anaesthesia.

I would suggest to Dr. Ronald Woolmer (p. 145) that ether is certainly a factor in chest complications and post-operation cough, since so many patients are excessive cigarette smokers and the bronchial secretion is much increased.

I am convinced that the dangers and failures as well as unpleasant sequelae are due usually to faulty technique, and the objections are very theoretical. For example, Dr. Robert Percival (p. 145) thinks that at sea one could not keep the head low; well, I was not thinking of a destroyer in mountainous seas, and I imagine the conditions for spinal analgesia could usually be quite easily attained. There would be nothing "unsafe" about it: only the discomfort of a possible headache. —I am, etc.

Hford

N. BEATTIE.

Penicillin in Ophthalmology

SIR.—In a leading article (Jan. 5, p. 17) you sum up recent publications on penicillin and contrast the effects of the agent with those of the sulphonamides in infections of the eye. While ophthalmologists would agree with much of your article there are three points which need qualification.

1. You state, "Though some experimental evidence has been advanced that they [sulphonamides] are effective in infections of the outer eye when used locally, it cannot be said that there is any real clinical support for these observations." I am convinced, from clinical experience, that the sulphonamides used locally are quite as efficient as penicillin in curing infections of the outer coats of the eye. There are individual cases that respond to sulphonamide but not at all to penicillin, while a certain number respond very pleasingly to penicillin. In blepharitis I find a great many more cases benefit from thiazamide ointment (mentioned in your columns, 1943, 1, 605) than from penicillin ointment, but a certain number resent thiazamide but respond to penicillin ointment. The case for sulphonamides by local application is still worthy of consideration.

2. In ophthalmia neonatorum Sorsby (quoted in your article) supplies interesting results from the use of penicillin drops. The obvious disadvantage is that it is a whole-time job for one nurse to carry out the treatment. Just as good and quick results are obtained by giving sulphonamides by mouth without the necessity for taking the infant into hospital or upsetting the mother/infant routine reaction. This is the chief ophthalmic condition where sulphonamide by mouth is indicated.

3. In trachoma, from experience of only a few cases, some are quite definitely relieved by sulphacetamide drops, while others do not respond or are actually made more irritable. I cannot say I have seen a clinical cure from this treatment. One case is worth special mention. No help whatever was obtained from sulphonamides by mouth or locally. A troublesome thick mucopurulent discharge has resisted all local treatment except penicillin. The latter has controlled the discharge and made life bearable for the last fifteen months. It has not cured the trachoma, but the natural cure, cicatrization, is slowly proceeding.

Obviously we must know more about the mode of action of both sulphonamides and penicillin, and perhaps more about the infecting organisms, before the correct choice of drug and best method of use can be determined. Neither penicillin nor sulphonamides make an ophthalmic "cure-all" yet.—I am, etc.,

Worcester.

I. LLOYD JORNSTONE.

Surgical Catgut

SIR.—It is with the greatest reluctance that I write to you a further letter on the subject of surgical catgut, but I feel that the letter of Sir Weldon Dalrymple-Champneys (Jan. 26, p. 147) requires an answer. He seems to be concerned with depart-

mental administration of some Act of Parliament; I was concerned with the freedom to use the material I wished to use, and not that which I am directed to use. I readily accept his corrections, but they appear trivial and do not affect my argument. I will refer to these points later.

Messrs. Thackray inform me that they are not allowed to import Davis and Geck's catgut. The Import Licensing Department refused the licence on the ground that the Directorate of Medical Supplies stated that ample supplies were available in this country, and also on the ground that it was still necessary to conserve foreign currency. Now either the Directorate of Medical Supplies believes that one catgut is as good as another or that the supplies available are as good as any that could be imported, or that we must make do with inferior material owing to the overriding political necessity for conserving foreign currency. It is in connexion with the last possibility that the vast sum expended on American cinema films makes this argument applied to the relatively small sum involved in importing catgut ridiculous.

With regard to the question of sterility, I had in mind (though for the sake of brevity I did not define my meaning) the loose surgical sense rather than the bacteriological. I meant that not only was the substance sterile when implanted in the tissues but it remained sterile. All surgeons, especially those with experience in bone surgery, will recollect many sterile substances which when implanted in human tissues become ultimately the seat of infection. The American catgut usually had a small amount of antiseptic (e.g., biniodide of mercury) in it to prevent this. The London Hospital catgut is similarly treated. And here I would like to acknowledge the courteous help I have received from the London Hospital Ligation Department since this correspondence has started. On their advice I am using 40-day instead of 20-day catgut in the abdomen, and so far it is satisfactory. I used to use 20-day Davis and Geck, and this seems to indicate a variation in units or the fallaciousness of their estimation. I realize the unit is more or less artificial and that each batch cannot be tested biologically for absorption rate. Incidentally, I may state that the raw material for the London Hospital catgut is imported from New Zealand. I have had no sepsis attributable to this catgut.

The relative merits of catgut can be determined only in human tissues and not in the laboratory, and if foreign catgut is excluded on commercial or political grounds then it is perfectly fair to say that these grounds are interfering with the scientific atmosphere. If English catgut is as good as foreign then it can stand up to competition. If it is not, then the sooner we import some the better. Coming events cast ominous shadows: control and direction threaten us in every direction, and I am concerned that we should not without the strongest and most overwhelming reasons submit to infringement of our liberty.—I am, etc.,

Hove.

H. J. MCCURRICH.

Paralytic Ileus

SIR.—Mr. Alan Shorter (Feb. 2, p. 177) gives an admirable account of some common causes of post-operative paralytic ileus and suggestions for minimizing these, with which I could not agree more. He continues with a scheme of treatment with which I could not agree less. It appears that even now we are not, in this country, fully conscious of the absolute necessity for maintaining intestinal decompression by means of suction-drainage in the prophylaxis and treatment of this most dangerous condition.

In America, where most of the pioneer work on intestinal decompression has been performed, particularly by Owen H. Wangenstein on duodenal suction-drainage and Abbott and his followers on intestinal suction-drainage with the Miller-Abbott tube, the need for suction-drainage is no longer questioned. The published evidence is too overwhelming. It is, I imagine, because our minds have been so long fixed upon the problems of war surgery that we have failed to keep abreast of modern developments which are now well beyond the experimental stage. Yet even that is surprising when we have so many of us seen the effects of continuous suction-drainage after operation for penetrating wounds of the intestines. The following com-

ments on the prophylaxis and treatment of paralytic ileus appear justified:

1. As Mr. Shorter describes, poor anaesthesia, rough surgery, dehydration, toxæmia, pain, exhaustion all play a part in the causation of paralytic ileus, and any scheme of treatment must attempt to eliminate these factors so far as possible. I agree entirely with the use of morphine, because it will relieve pain, anxiety, and sleeplessness. I do not believe it has any helpful direct effect upon peristalsis; indeed, in big doses its direct effect is probably harmful. For that reason I hold that repeated small doses—gr. 1/8 (8 mg.) eight- or twelve-hourly after an initial gr. 1/4 (16 mg.)—should be employed.

2. Mr. Shorter is undoubtedly correct in saying that the precipitating cause of ileus is the failure to prevent slight and early post-operative distension from developing into frank paralytic ileus. This is best prevented by post-operative intestinal decompression by duodenal suction-drainage in every case in which ileus is considered a likely hazard, particularly if the patient starts off post-operatively with an initial pathological dilatation (e.g., after operative relief of obstruction). The whole aim and object of this decompression is the prevention of the vicious circle which is the inevitable result of passive dilatation if it is allowed to reach a certain stage, dilatation causing paresis and paresis allowing further dilatation.

3. As regards the use of intestinal stimulants, I can do no better than quote Holt, who says: "Purgatives and drugs which normally stimulate peristaltic action are contraindicated. The habitual use of such drugs as pituitrin, eserine, and acetylcholine in the post-operative treatment of these cases is to be strongly condemned. Occasionally their use produces the dramatic relief of intestinal distension, but their successes are far outnumbered by the majority of cases which are made worse by such treatment. It should be borne in mind that the cause of the trouble is a paresis of the intestinal muscle, which will resume its function when it has recovered its tone. This recovery is best facilitated by resting the gut as much as possible."

4. If ileus develops in the absence of, or in spite of, duodenal suction-drainage intestinal decompression with a Miller-Abbott tube is obligatory. The phrase "gastric suction with a Miller-Abbott tube," used by Mr. Shorter, is a contradiction in terms. The stomach is emptied with a large stomach tube and the Miller-Abbott tube is then passed into the small intestine. Abbott describes the subsequent progress thus: "Whether the cases develop following intraperitoneal procedures or reflexly following injuries or operations on other parts of the body, a tube in the small intestine will progress from region to region, restoring peristaltic activity, until the balloon is expelled by rectum."

5. Naturally, fluid and chloride must be replaced by vein (and, it appears, protein too), but the enormous volume of fluid withdrawn by suction does not mean any greater necessity for intravenous fluids, for stagnant fluid left in the dilated intestine is just as much lost from the general circulation as that withdrawn by suction.

6. The principle of providing physiological rest for the dilated intestine appears to me a much sounder one than an attempt to coerce the gut into contracting while it is dilated and therefore at a great mechanical disadvantage, and the results I have had, using decompression and no intestinal stimulants, have confirmed me in this belief.

—I am, etc.,

Kensington

SIR,—Most doctors would concede that a personal experience was worth several of those of their patients. When I had paralytic ileus for a short period following a resection of gut some years ago I was treated with ox-gall enemata and injections of prostigmin. It was the most painful and exhausting business I ever hope to experience. And when, after flogging my bowel in this manner, the sister was able proudly to show the surgeon a small faecal object in the bedpan, even he was compelled to observe somewhat gloomily that "one swallow did not make a summer." By contrast those patients who at this time were beginning to be treated by morphine, suction, and intravenous fluids, enemata being withheld until bowel sounds were audible—these had a far smoother passage.

Perhaps you will also permit me to pour scorn on the efficacy of a flatus tube in this condition. He is a "poor fish" who cannot empty his own lower rectum. The tube does nothing for his distension and is very uncomfortable to sit on.—I am, etc.,

R. A. F. West Kirby.

MICHAEL HARMER.

Stethoscope versus X Rays

SIR,—May I summarize the results of my experiences in a few sentences.

1. The x-ray skiagram is indispensable for both the quantitative and qualitative analysis of lung tuberculosis, leave alone for the diagnosis of neoplasms and for the assessment of dust diseases. Although thoroughly and skilfully performed sounding will continue to be used for guidance, especially in the practitioner's consulting room, the student should be taught that completely negative findings must not be considered as ruling out pathological changes of considerable extent.

2. The interpretation of the auscultatory signs has profited substantially from co-operation with radiology. We have learned that more often than not bronchial breathing is missing in the presence of a cavity, which should be suspected as well from other auscultatory phenomena; that fibrosis and shrinkage may produce bronchial breathing. Diagnosis with the stethoscope has gained in accuracy.

3. There are not few occasions when the findings of auscultation are valuable or even decisive—e.g., for the identification of a cavity buried in the uniform opacity of fibrous, exudative, or caseous tissue. The evaluation of the respiratory functional potential is impracticable without the stethoscope; bronchial secretion and bronchial spasm with their detrimental effect on the air passage will be heard, but, as a rule, not seen. The importance of the auscultatory findings in cases of bronchiectasis need not be stressed.

4. The stethoscope is likely to provide a better opportunity for the doctor to concentrate on the general aspect of the patient than the x-ray examination, and to facilitate psychological contact.—I am, etc.,

Westmorland Sanatorium, Grange-over-Sands.

E. FRAENKEL.

SIR,—In reply to the letter of Dr. J. Frankland West (Feb. 2, p. 182) the data given in his letter merely show that the interpretation of an x-ray film by a particular radiologist was an incorrect one. The radiograph did, in fact, show the pulmonary lesion in question, and is not, therefore, to be condemned as having missed an early tuberculous lesion, but it is the interpretation of that skiagram that has been found to be in error. Surely general practitioners as a whole are not to be condemned because one practitioner has missed diagnosing a case of acute appendicitis. Does Dr. West claim that he himself is infallible?

It is not always possible for the radiologist to state the aetiology of a pneumonic consolidation from the skiagram. In some cases further details are necessary, such as the result of the clinical examination, together with laboratory tests, etc., before a diagnosis can be made. It would appear to me (without having seen the film) that the report should have read: "There is loss in translucency in the affected zone or zones of the lung." This may be due to tuberculosis, atypical pneumonia, lobar pneumonia, or lung abscess. The subsequent progress under serial x-ray observation will help in the diagnosis together with clinical and laboratory evidence.

Chest physicians and tuberculosis officers are well acquainted with segmental and lobar areas of consolidation which are found subsequently to be tuberculous in origin. In fact, mass radiography is responsible for the detection of an appreciable number of similar cases in persons who are completely symptomless. This type of tuberculous lesion is, as a rule, found in young adults, especially young women between the ages of 14 and 25. Dr. West's case had both symptoms and physical signs, whereas the value of mass radiography is in the x-ray of apparently healthy people for the detection of early disease. That mass radiography has fully justified itself as a means of detection of previously unsuspected disease is now beyond question. Inspection of published results confirms this statement.—I am, etc.,

Nottingham.

A. E. BLYNOR.

SIR,—Dr. F. Kellermann's letter (Feb. 2, p. 182) puts the matter in a nutshell. The last paragraph embodying the results of the test sponsored by the American Trudeau Society is particularly interesting. *Finis coronat opus.*

Even those of us who have studied under masterly exponents of clinical examination of the chest, such as the late Sir Robert Philip, founder of the tuberculosis dispensary system, have been

compelled reluctantly years ago to realize the limitations of the stethoscope. I may be confidently stated that anyone who claims to diagnose early (I say advisedly "early") pulmonary tuberculosis or for that matter carcinoma, with the stethoscope alone is a fool a charlatan, or a superman. X-ray examination of course has its shortcomings, and experienced specialist radiologists with all modesty are themselves among the first to admit this. However, with the progress of research the x-ray plant is likely to become an instrument of greater precision in the near future.

Although this correspondence is primarily concerned with the stethoscope and x-rays it may not be out of place to refer briefly to examination of the sputum. This line of investigation has been sadly neglected, particularly in those patients who cannot or will not attend the hospital outpatient department or clinic and are labelled "debility," "anaemia," "chronic bronchitis," etc. Even in certain cases which have been subjected to intensive clinical and radiological observation the finding of acid-fast bacilli in the sputum is often the decisive factor in diagnosis. Beware, however, the single sputum-positive report unless adequately supported by clinical and x-ray evidence. In such a case repeated sputum examinations are necessary.

It is essential, therefore, to take an unbiased, broad, flexible view of the whole subject, and in addition to a carefully taken history, to use every available method (clinical, x-ray, and laboratory) for diagnosis and assessment are to be thorough and complete. The majority of us would prefer, I imagine, to hear less of "the stethoscope versus x-rays," and more of "the stethoscope plus x-rays, plus sputum examination," with closer co-operation between the clinician, radiologist, and pathologist—I am, etc.

Tuberculosis Dispensary, Chester

DAVID W. TOLGH

D.D.T. Poisoning

SIR,—I have read the comments on our article "Fatal DDT Poisoning" (Dec 15, 1945, p. 845) by Dr I. E. Balaban (Jan 26, p. 147) and wish to give further reasons why we concluded the cause of death in the child was due to DDT rather than to the kerosene. In addition to Experiments I and II described in our article, we carried out other experiments which were not included for the sake of brevity and because they were of dosage apparently outside the minimal oral dosage of 5% DDT in kerosene required to cause toxic effects. They have now perhaps some interest in respect to the question raised by Dr Balaban as to the toxicity of kerosene to baboons. The experiments (including Experiments I and II of the article) were as follows:

Expt No.	Weight of Baboon	Dose (Orally)	Dose in ccm. per kg Body Weight	Result
	lb	kg		
Ia	7 (3.2)	10 ccm 5% DDT in kerosene	3.1	Baboon unaffected
	6 (3.0)	9 ccm kerosene	3.0	
Ib	7 (3.2)	15 ccm 5% DDT in kerosene	4.7	ill "
II	7 (3.2)	15 ccm kerosene	4.7	unaffected
	7 (3.2)	30 ccm 5% DDT in kerosene	9.4	died (1 hour)
III	6 (2.7)	25 ccm kerosene	9.4	unaffected
	6 (2.7)	27 ccm 5% DDT in kerosene	10.0	died (45 mins)
IV	6 (3.0)	10 ccm kerosene	10.0	unaffected
	6 (3.0)	60 ccm kerosene	22.2	"

Experiment Ia was a preliminary one in which the dosage per kilo was the same as that of the child (10 kg body weight ingesting 30 ccm 5% DDT in kerosene). Experiment III was supposed to aim at a dosage between that of Experiments I and II, but owing to a miscalculation only confirmed the results of Experiment II. Experiment IV is an observation from another series of experiments on DDT not related to the above investigation. Necropsy on this animal 30 days later showed no abnormality macroscopically or microscopically.

The results and deductions made were: (1) Toxic effects were only seen in the series receiving kerosene plus DDT, though none of the control series was affected. (2) It is therefore

reasonable to assume that the toxic effect in the baboon was due to the DDT. (3) It will be noted that the baboon mentioned by Dr Balaban (Experiment II, 9.4 ccm per kg) had more than three times the amount of kerosene ingested than the child (3 ccm per kg) and that the baboon in Experiment IV (22.2 ccm per kg) had no less than seven times the dose with no ill effects.

Dr Balaban mentions that DDT in organic solvents can be potentially dangerous, but his quotation of the annotation in the *Journal* (March 10, 1945, p. 338) is so written as to discredit this statement. The annotation quoted suggests that DDT dissolved in organic solvents would have to be administered in exceedingly large volumes to be toxic. That this estimate of the low toxicity of DDT to human beings is a little too optimistic is surely shown by the later experience of Wigglesworth (1945) and Case (1945) who both found DDT dissolved in organic solvents toxic to human beings even by absorption.

It is true, however, that the evidence regarding toxicity of kerosene is conflicting. Waring (1933) described 2 deaths out of 23 cases, Nunn and Martin (1933) 6 deaths out of 6 cases, and Farbaugh (1936) 5 deaths out of 120 cases of kerosene poisoning by ingestion. More recently Lesser *et al* (1941) describe 1 fatal case out of 32 cases in children aged 1 to 3 years, and dosage varying from one swallow to half a glass of kerosene. The fatal case was that of a child aged 18 months who ingested 150 ccm of kerosene and died within 5 hours. They also quote the case of an adult who ingested 7.0 ccm of kerosene with apparently no ill effect. Deichmann *et al* (1944) describe the case of a child aged 1 year who died 9 hours after drinking one mouthful of kerosene. They calculate that the fatality rate of published cases is 6.7%. Dr Balaban's criticism is fair criticism in that kerosene can cause death in small children.

At the time of writing the article we had no access to the literature on kerosene published above, but our baboon experiments implied that the grade of kerosene used (and there are many grades—*vide* Deichmann *et al*) was non-toxic even in large doses. From the experiments of Smith and Seelman (1944) and Woodard *et al* (1944) who found that for small mammals lethal oral doses of DDT in vegetable oil were 1.0 to 6.0 mg/kg body weight, we calculated that a 10 lb child would have to ingest 20 to 120 ccm 5% DDT in kerosene to show lethal effects. The fact that the child died ingesting 30 ccm 5% DDT in kerosene was thus in accordance with these deductions—I am, etc.

The E.S.R. Technique

SIR—Dr J. W. Shackle (Feb 2, p. 181) says "It is not serum, of course, but let that pass." Hutchinson and Hunter (*Clinical Methods*) call the clear fluid that settles at the top when blood is allowed to stand "serum" fourteen times in three pages (600-2). What is good enough for them is good enough for me. Dr Shackle states that my remark that "the higher the column of blood the greater will be the amount of clear serum to be read off" is an "error of great magnitude." But when I take two Westergren tubes and fill one up to 200 mm and the other up to 100 mm with the same blood and find at the end of an hour, as I have done repeatedly, that the length of the column of clear fluid above the erythrocytes in the former is precisely double that in the latter, I must take leave to believe my own eyes rather than Dr Shackle's statement that "it is just positively not true." His Gilbertian accusation that I might just as well say that I (or preferably he) would drown five thousand times faster in the Pacific than in the deep end of a swimming bath is like "the flowers that bloom in the spring," and has "nothing to do with the case."

Presumably one's drowning rate would be equal in either eight or eight thousand feet of water.

"No reputable firm sells sedimentation tubes with jagged ends"; but my tubes were made, or marketed, by a reputable firm, and they have ends jagged, or irregular, enough to let in air unless I wet my finger.—I am, etc.,

Stowmarket.

H. S. GASKELL.

Tuberculosis in Childhood

SIR,—The magnitude of this problem may be assessed by the Lancashire figures. In a population varying during the war years from 1,900,000 to 1,837,000 the deaths from tuberculosis in children have been as follows:

	Five-year Averages			1943	1944
	1928-32	1933-7	1938-42		
Pulmonary tuberculosis :					
Aged 0-5 years	7	3	7	8	8
Aged 5-15 years	22	15	9	6	4
Non-pulmonary tuberculosis :					
Aged 0-5 years	75	57	59	56	66
Aged 5-15 years	43	34	25	27	22

The deaths from meningitis in children 0-5 have been a little less than half the total for all other age groups combined (i.e., up to 65). Dr. Gaisford in his article on primary tuberculosis in childhood (Jan. 19, p. 84) speaks of "scores of infants dying from tuberculous meningitis." In the administrative county area in a population given above the deaths in the age group 0-5 in 1943 were 36.

How can tuberculous meningitis be greatly reduced or prevented? In the Lancashire research on *The Fate of Young Children in Tuberculous Households* (C. Tinling & Co., Ltd., Liverpool, London, and Prescott, 1929, p. 37) one of the conclusions ran:

"The death rate from non-pulmonary tuberculosis of children exposed to risk in tuberculous households from an adult with positive sputum was greatly in excess of the rate from the same cause in the geographical county of Lancaster serving as the 'control,' the rate being: nine times greater in the age group 0-1; fourteen times greater in the age group 1-2; nineteen times greater in the age group 2-5. This great excess of non-pulmonary tuberculosis is mainly due to deaths from tuberculous meningitis, which accounted for two-thirds of the mortality in the non-pulmonary group, ages 0-5."

When, therefore, we more thoroughly find, isolate, educate, treat, and rehabilitate the adult positive case this distressing mortality in young children will be prevented, and then, and only then, will the tuberculosis physician and the paediatrician be satisfied.—I am, etc.,

Preston

G. LISSANT COX.

SIR,—Reluctant to enter into the somewhat veiled controversy about childhood tuberculosis and its management, on which opposed views threaten to become overt in the correspondence columns of your *Journal*, I must disagree with the assertion in Dr. Stephen Hall's letter (Feb. 2, p. 180) that the importance attached to this disease by paediatricians seemed to him "almost dilettante." The implication that a section of our profession could magnify the significance of a disease, preventable, yet fatal to more than 2,000 children annually in England and Wales, is false. In 1936-8 the average yearly number of deaths from primary tuberculous meningitis alone was 2,322, and in 1941 was 2,933, 80% occurring in children. It is true that adult-type tuberculosis kills ten times as many victims and causes 100 times as much suffering and ill-health, but such comparisons lead us nowhere. Biologically it may be no less desirable to save the life of one child than that the lives of ninety and nine phthisical middle-aged should be prolonged. I am certain that there is no real divergence of opinion on the paramount need to safeguard the nation's children.

One reads on every hand the categorical imperative: "Protect your child against diphtheria," but child deaths from tuberculous meningitis are at present of a similar order of magnitude in this country. At some future date we may see B.C.G. vaccination (and the consumption of pasteurized milk) advocated with equal colour and emphasis on our hoardings,

cinema-screens, and in our newspapers. I am unaware that our tuberculosis service is promoting research on these lines in contrast to the practice in Scandinavian and other countries of conferring by this means a partial immunity on newborn infant "contacts" and Mantoux-negative reactors at risk in the older age groups. For this reason alone we have little cause for complacency.

Dr. Stephen Hall also makes the mistake (but in reverse) that Dr. R. M. Orpwood objects to in his letter (p. 180) by placing in his turn an excessive reliance on local mortality statistics, while tending to disregard the clinical impressions of others. That "it doesn't seem a great problem" does not hold everywhere. In the *Medical Officer* (June 24, 1944) I wrote of our experience of tuberculous meningitis in an urban community of 300,000 people during the first four years of war. Then we had 97 deaths, of which 74 were in children under 15 years, 53 in those under 5 years. (During the same period we lost 56 children under 15 years from diphtheria.) Due to the fluctuating number of the child population at risk we could only guess at the true occurrence rate, which may have been 100% higher than in peacetime.

As we have only one children's hospital it is possible that any paediatrician might truthfully aver that he had seen one or more "scores" of meningitis deaths over a short period of years. This probability was even likelier in London, where Dr. W. Allen Daley (*Journal*, Oct. 10, 1942, p. 417) revealed that the rate of new cases of tuberculous meningitis per 1,000 living was 250% greater in children in 1941 compared with 1938.

In infants tuberculosis is one of the most fatal of diseases; at pre-school age it becomes less so, and is comparatively harmless during school life. Age is thus a factor in determining mortality, but more critical perhaps is the presence of contact with a continuing source of infection. Many more "preventoria" are necessary, so that we may be able to rescue for a time from the hazards of their environments the smaller children from the poor and infected families.

In a city of 60,000 children 50 to 60% will have passed safely through their primary infections when they reach school-leaving age. By simple arithmetic one can calculate that, if all this infection and disease could be detected (by tuberculin surveys and mass radiology) and were evenly distributed in time, that city would require a children's sanatorium of 1,000 beds, capable of dealing with 2,000 to 3,000 cases each year. The contention commonly aired by paediatricians, that, ideally, all primarily affected children should be treated in sanatoria, scarcely seems defensible, nor would it be possible to effect.

At Papworth no child out of several hundreds born there in 30 years has died from generalized tuberculosis. Tubercle in childhood loses many, if not all, of its potentialities for disease and tragedy where housing is adequate, work and wages secure, diet satisfactory, combined with close medical supervision of those living in the infectious milieu. That lesson, taught so that he who runs may read, has yet to be learned by most of us. When it is, our wrangles on this subject will lapse into mere dialectical exercises. In the meantime we must constantly use our own influence to bring about this socio-economic amelioration.—I am, etc.,

Kingston-upon-Hull

R. HARDY.

SIR,—May I take up a point in the concluding remarks of Dr. Wilfrid Gaisford in his excellent review on primary tuberculosis in childhood (Jan. 19, p. 84). Quoting Nelson he writes: "The ideal procedure would be for him [the average general practitioner] to do tuberculin tests on all children . . . and order x-rays on all positive reactors and their contacts." How wonderful it would be if this could be fulfilled! From my own experience of general practice I have often been gripped by a sense of terrible frustration, sometimes amounting to anger, when faced time and time again by a household containing a tuberculous adult and the bairns running freely around—nobody caring. The tuberculosis authorities do not appear to have the staff to visit all such cases, and in any event where can the children go? The terrible housing shortage caused by the war accentuates the problem. The general practitioner has hardly the time to do routine Mantoux tests on all children and x rays are not in his power to order.

It is this last point which is of decisive importance. To-day the x-ray examination of the chest is as much a part of a

clinical examination as percussion or auscultation. When René Laennec invented the stethoscope more than 100 years ago he gave to the profession a modern scientific instrument which proved invaluable. For more than 30 years it has been impossible to think of a doctor without also thinking of a stethoscope.

Röntgen's discovery of x rays has opened a new door, but as yet the general practitioner is not in possession of this mighty weapon in the pursuit of tuberculosis. The possession of his own x ray plant is beyond his means but to day a new system in the organization of medical practice presents us with an opportunity to give the general practitioner what he has long waited for—his own x ray plant where he may radiograph the chests of his own patients. I refer to the health centres which the Minister of Health will introduce when the health Bill becomes law. The general practitioners and others interested in his work must insist that in these new institutions there must be modern x ray plant and a skilled radiographer so that G.P.s may readily radiograph their own patients, whether children or adult. If this is done, and full facilities for the scientific practice of medicine are given to the G.P., the much talked about "shortcomings of the average general practitioner," which frequently recur in scientific books and periodicals, not to mention the lecture to students by the clinical teachers themselves, could be remedied before many more years have gone by—I am, etc.

Newcastle-upon-Tyne

P. W. ROE

Sulphonamide Control of Streptococcal Epidemics

SIR,—May I call attention to a statement in the annotation under the above heading (Feb 2, p 168) to the effect that "mass chemoprophylaxis did not induce sulphonamide hypersensitivity among the men, nor did it produce sulphonamide-resistant strains of streptococci" (italics mine). I have not yet had the opportunity to see the paper by Commander Coburn referred to, but in a report on the whole of this chemoprophylactic work (Navmed 284) published by the Bureau of Medicine and Surgery, Navy Department, Washington, D.C., in 1944 or early 1945, there is a footnote (p 33) which says "During the summer months (since this report went to press) clinical and bacteriologic findings have indicated that strains of Types 19 and 17 recovered at this naval activity are resistant to prophylactic doses of sulfadiazine."

Much more important is the paper published in the *Journal of the American Medical Association* for Dec 1, 1945 (129, 921) by Epidemiological Unit No 22, which gives an account of a major epidemic of streptococcal disease which occurred in one of the camps where sulphadiazine-resistant strains became predominant (Types 19 and 17). There seems to be no doubt that the adoption of mass chemoprophylaxis was, in fact, followed by the appearance of these resistant strains, in this instance at any rate—and that it had serious consequences.

It is a disquieting reflection that these sulphonamide-resistant streptococci may have been widely distributed in the world by the trainees of this and other U.S. camps—I am, etc.,

LEONARD COLEBROOK

Quinine for Induction of Labour

SIR,—In your issue of Jan 19 the Ministry of Health gives notice that quinine may now be used for the induction of labour. It is unfortunate that a thoroughly bad practice which is productive of many stillbirths each year should thus be revived—I am, etc.,

London W 1

F. NEON REYNOLDS

The Disabled Persons Register

SIR—Dr J. S. Laurie is to be commended for giving careful thought to the Disabled Persons Act and the duties which arise therefrom (*Journal*, Feb 2, p 183) but unfortunately his interpretations are misleading, his conclusions erroneous, and his observations unjust. Employers who advise their employees to register are not "unscrupulous." Employees who accept such advice are not "victimized." There is no new "racket." In refusing to give a certificate or to assist in registration because a disabled man is already in regular employment, Dr Laurie displays misunderstanding of the Act. He argues that if a

patient has hitherto been regularly employed and is presumably a valuable employee, he cannot be substantially handicapped. But the disabled person who is once given the opportunity is nearly always a valuable employee. The very purpose of the Act is to see that every disabled person becomes a valuable employee and that every disabled person is in regular employment. It will not be suggested as soon as we have succeeded in this purpose that none are disabled and none worthy of registration. Meanwhile, is a man to be penalized because he has done for himself what others are trying to do for others? Is an employer to be penalized because for some years he has done a duty which is now to be forced upon him? One disabled man may already have gained employment, whereas another is hoping shortly to gain employment, in each case the problem is the same—is there a handicap in the open labour market, in competition with his fellows, in these days when there may be unemployment as well as present days when there is almost full employment, not for an employer for the most skilled work which he can take and keep on his merit? If there is a substantial handicap he should be registered. If there is no substantial handicap he should not be registered.

In many cases the decision is easy, and a disabled man may so grave that there is obvious need for protection or even some times for the special conditions of sheltered occupation, or on the other hand, the disability may be so trivial that there is clearly no need for registration. In such cases the Disablement Rehabilitation Officer will accept the recommendation of the patient's doctor and act accordingly. In other cases the decision is not easy—it is a border line case. But still there need be no anxiety on the part of the doctor, the decision is not imposed on the G.P. All that is required is a simple statement of the functional capacity of the patient on one of the official prepared forms or on any certificate which the doctor may prefer. The decision as to whether or not registration is warranted will then be made by the Disablement Advisory Committee of the region, a committee of employers, employees and doctors which will maintain reasonable uniformity throughout the region and in due course, with added experience, throughout the country.

It may well be that in early days some patients will get at least temporary admission to the register who a justification for registration is slender. If this does happen no serious harm will have been done. But the opposite danger is very real. The quota of disabled persons who must be engaged by every employer has been established provisionally at 2%, but the figure will be determined from time to time in accordance with the number of persons on the register. If any large number of disabled persons fails to register through pride or indifference, through failure to recognize the advantages to be gained or through neglect of their responsibility to others who are disabled, the quota will be lower than it should be and the whole purpose of the Act will fail. It is therefore the duty of all employers, and likewise of all doctors, to see that every disabled person with a genuine handicap in seeking or keeping employment is recommended for admission to the register. If any doctor is in doubt he should ring up the nearest Exchange and ask for the Disablement Rehabilitation Officer who will be honoured and delighted to accept an invitation to co-operate—I am, etc.,

REGINALD WATSON JONES

Chairman of the Medical Committee, National
Advisory Council of the Ministry of Labour
and National Service

London, W 1

SIR—Dr J. S. Laurie is exposing not a "racket" but what is probably a commendable effort on the part of enlightened employers to ensure that their disabled employees take advantage of their rights under the Disabled Persons (Employment) Act, 1944. If there is a weakness in the Act it is not that too many but too few disabled people will register, but I believe this weakness will, in time, be overcome by the guidance of well-informed doctors and employers and the Press. Dr Laurie will find his difficulties resolved by a visit to the Disablement Rehabilitation Officer at a labour exchange who will, I have found, gladly explain the workings of this excellent Act and the method of assessing "border line" cases—I am, etc.,

Cambridge

GORDON H. MCCracken

Obituary

SIR JOHN BROADBENT, Bt., D.M., F.R.C.P.

Sir John Broadbent, consulting physician to St. Mary's Hospital, to King Edward VII Sanatorium, Midhurst, and to the London Fever Hospital, died on Jan. 27 at his country home near Wendover in Buckinghamshire.

John Francis Harpin Broadbent was born on Oct. 16, 1865, the eldest son of Sir William Henry Broadbent, M.D., F.R.S., first baronet, one of the leading London physicians and clinical teachers in the latter part of the reign of Queen Victoria, who had been physician to three generations of the Royal Family. John Broadbent, of Yorkshire descent on both sides, was educated at Rugby and Oxford, and entered St. Mary's Hospital while his father was still on the active staff there. He graduated M.A., B.M., B.Ch.Oxon in 1892, proceeded to the D.M. degree in 1894, and was elected F.R.C.P. in 1904. At St. Mary's he held the posts of house-physician, house-surgeon, casualty physician, and assistant pathologist and curator of the pathological museum, and became physician to out-patients in 1905. He was elected to the full staff in 1913 and for ten years was Dean of the Medical School, devoting much time and energy and good will to the duties of that office during a difficult period. He retired from the deanship in 1920 and from the active staff of the hospital in 1930. He examined in medicine for the Royal College of Physicians for four years and served on the Council in 1923-5.

Sir John Broadbent, who succeeded to the title in 1907, was secretary of the Section of Medicine at the Sheffield Meeting of the British Medical Association in 1908. In later years he was President of the Medical Society of London and of the Harveian Society of London. He had collaborated with his father in the book *Heart Disease and Aneurysm of the Aorta*, which reached its fourth edition in 1906; his younger brother, Dr. Walter Broadbent, formerly physician to the Royal Sussex County Hospital, Brighton, undertook the editorship of *The Writings of Sir William Broadbent*.

Sir John Broadbent married a daughter of G. P. Field, aural surgeon to St. Mary's, and had four children. Unlike his father, who was a man of robust and outspoken nature, he did not make an immediate impression in the wards or in the lecture-room, but students could feel his warm concern for their welfare and that of the hospital and medical school; and the value of his quiet teaching at the bedside was reinforced by the courtesy and consideration he showed to patients.

H. D. MCKINNA, M.C., M.B.

The very sudden death of Dr. H. D. McKinna of Nottingham came as a severe shock to his many friends. He had been in his usual high spirits, and was enjoying, with all his well-known vigour, the games at a New Year's Eve party at the rooms of his church, when he suddenly collapsed and died.

Henry Drummond McKinna was born at Huddersfield 47 years ago. He was educated at Huddersfield College and Silcoats School, and took his medical degree at Edinburgh University. In the 1914-18 war he was a second lieutenant in the Argyll and Sutherland Highlanders. It was characteristic of him that he joined up before he was of age. He was severely wounded in 1917, and won the Military Cross. On recovery he completed his medical studies at Edinburgh. After graduating M.B., Ch.B., he was house-surgeon at the Nottingham General Hospital, where he met his wife, Dr. Eva Young. They were married in 1924, and had two sons. He settled in practice at West Bridgford, Nottingham, in 1931, first as partner to Dr. Blurton, and on his retirement with Dr. S. C. Mattock. Apart from his large practice, he found time to act as a very capable assistant in the department of dermatology at the Nottingham General Hospital, and also as joint secretary of the local branch of the B.M.A. He was a member of the council of the Nottingham Medico-Chirurgical Society. He was ever keen on the welfare of his brother practitioners, and took endless pains at both local and representative meetings on their behalf.

The following tribute comes from J. G. B. and S. C. M.:

Dr McKinna was worthy of the title of doctor, for he never spared himself in his efforts to bring help and comfort to his patients. He kept well abreast of the times, and any new treatment was not long withheld from his active and capable hands. When most of us would tire of the ordinary routine, he would still have that

buoyant enthusiasm that marked all his work and made acquaintance with him such a treasured memory. Working day and night, he seemed to have unbounded energy, which, in the light of our knowledge now of the frail body that housed this gallant spirit, is nothing short of a miracle. His help was always generously given, no call on his precious time went unrewarded, he would come with a smile and an assurance that was a comfort in the time of doubt. Light did not come to him from eastern windows only, he found it in all directions; where one saw shadows he saw hope, and because, of this great faith and noble outlook we will all miss him the more. Despite his very active life, he found a little time to play a few holes of golf, or the break of a day or so to cast a fly.

What a delightful companion he was! always ready for the fray, never despondent if things did not go right, never critical of failure, ever ready with that well-known smile to give encouragement and advice. How well he could give advice too! never leaving behind any sour taste, but usually something sound and of much help. It would be impossible to write of all the virtues of this great-hearted little man; only can we say a few little words which cannot express what the heart would. To his widow, to Colin and Alan, we would give our sincere sympathy in the days of their great sorrow.

F. E. SCRASE, F.R.C.S., D.P.H.

Dr. Frank Edward Scrase, who died at Newton Abbot on Feb. 4, was appointed medical officer of health for the Metropolitan Borough of Hampstead in 1912, and held office until 1932, when he retired on attaining the age limit. He studied medicine at Bristol and St. Bartholomew's Hospital, qualified in 1893, and took the F.R.C.S. in 1896. He was a member of the first Borough Council of Hampstead from 1900 to 1903, but did not seek re-election. In 1905, having taken the D.P.H., he acted as M.O.H. for a few months during the period between the death of Dr. Herbert Littlejohn and the appointment of his successor. He became honorary deputy M.O.H. in 1908, and in 1912, when the senior office again fell vacant, he was elected to the position.

Dr. Scrase was a man of kind disposition, and very popular among his colleagues. As a public health official he believed in steady, consistent, ordered progress; and during his term as M.O.H. he maintained the high standard which had been set by his predecessors. He was a member and at one time chairman of the Metropolitan Branch of the Society of Medical Officers of Health. In 1928-9 he was chairman of the Hampstead Division of the B.M.A. During his 21 years as M.O.H. he directed the development of many public health services, especially those connected with the campaign against tuberculosis, including the activities associated with the municipal tuberculosis dispensary at Kilburn; and the movement for a pure milk supply free from tuberculous infection. It is perhaps in maternity and child welfare more than in any other section that the gratitude of Hampstead is due to Dr. Scrase. His years of private medical practice before undertaking public office stood him in good stead in this; and the development of this work, as with that connected with tuberculosis, was conducted with the good will and help of the local medical profession. Under his advice and guidance a comprehensive scheme was developed; antenatal clinics were established, health visitors and other staff were appointed. In some particulars, notably in the careful investigation of all the circumstances of each case of illness or death among parturient women and of every infant death, Hampstead has been among the pioneers. Dr. Scrase undertook this work personally many years ago, and a medical subcommittee of the Borough Council has continued the work. The low infantile mortality of Hampstead has for many years been remarkable. Dr. Scrase's interest was not only concerned with infants, however, and many years ago he reported: "In a borough like Hampstead no child should begin school life with any disease or physical defects that could have been prevented or mitigated during the first five years of life by any action that ought properly to have been undertaken. A little effort spent in this direction on young children will, in all probability, result in the diminution of the number of physically unsound workers and potential parents." Many other references could be quoted from his annual reports which indicate the wideness of his outlook and length of vision. Next to work among women and children, Dr. Scrase's chief interest lay in housing, as his many outspoken and illuminating reports have borne witness.

W. E. THOMAS, M.D., J.P.

Prof. R. M. F. PICKEN writes:

Wales has lost a prominent and distinguished member of the medical profession by the death of Dr. W. E. Thomas. Although he was a busy and successful practitioner he had taken an active part in local affairs since the inauguration of the modern system of local government in the last decade of the nineteenth century, serving both on the Rhondda Urban District and Glamorgan County Councils. His medical knowledge and his experience in local government

made him a natural choice as a representative on bodies concerned with health and education. Thus he was a member of the Court of the University of Wales, of the Court of Governors and Council of the University Colleges of South Wales and Monmouthshire, of the Council of the Welsh National School of Medicine, of the Board of Managers and Council of the Welsh National Memorial Association, and of the Board of Management of Cardiff Royal Infirmary. Up to the end of his life he continued to take a very active interest in the affairs of the Medical School and of the Welsh National Memorial Association, being chairman of the Medical Committee of the latter body. The prominent part he took in the central and local activities of the British Medical Association is too well known to need more than mention.

Thomas had not the Welsh gift of oratory. He was at his most vigorous in committee. He read and mastered his agenda papers and never accepted unthinkingly the official or majority view on any subject. He was highly argumentative and, while he watched carefully the possible effects of decisions on medical practice, his primary concern was the best interest of the community. He was a keen Welsh patriot and concerned that Welsh men and women should have a square deal where appointments were concerned, but he was equally determined that the best candidates should be appointed to posts irrespective of their nationality, as the best means of serving the interests of Wales.

Like many other people who are individualistic and inclined to controversy, Thomas was a most kind and reliable friend. If you had a good case requiring support he could always be relied upon to give it. He knew the inner workings of local government in Wales, so that his advice and help to younger men were invaluable. There are many who will miss his presence and his support.

Dr. IVOR J. DAVIES, consulting physician to the Cardiff Royal Infirmary, writes:

I wish to add a personal note to Dr. Arthur Jones's tribute. Dr. W. E. Thomas was our family doctor and everyone at Pentre and neighbourhood had a very warm affection for him. To his exacting colliery duties he added a large private practice. It is remarkable how he managed to do it all—professional, B.M.A., and public duties—so easily and well. "W. E." was quick but safe, methodical and very practical, and always worked to a strict programme or he would never have been able to accomplish so much, and so continuously over half a century. Truly an amazing record, and the secret probably was that he had an exceptionally sound knowledge of modern medicine, an intense love of his profession and fellow men, and never wasted any nervous energy in his work. The early years of his practice were grim days in the Rhondda Valley, for there were no inter-valley roads at that time and no playing fields except for a few reserved for the leading football clubs. It was not until the Miners Welfare Commission became law that we secured recreation grounds—much to "W. E.'s" joy, for the collier was always first in his thoughts. On meeting him at Pontypridd when Glamorgan played its first championship match in the valleys instead of exclusively at Cardiff or Swansea, he remarked, "Now at last we shall see first-class cricket in the valleys." He was keen on sport, and particularly rugby, and never missed an international match, and was usually seen in the company of his old friend Dr. D. Roeyn Jones (president of the Welsh Rugby Union). He was proud of his alma mater—Edinburgh—and revered its great men. After attending a meeting of the Association of Physicians at Edinburgh I referred to its fine clinical demonstrations, when he sharply replied with that characteristic twinkle and shake of the head, "We were always foremost in clinical medicine, and several of your best men in London were Edinburgh graduates." "W. E." was a close friend of the late Earl Lloyd George in the great days of Liberalism, but his political leanings never lessened the miners' unfailing regard for their "doctor." He had a great love of Wales, its literature and music, and spoke excellent Welsh, for he came from the North. He was an elder at our nonconformist chapel, which he most generously supported throughout the long period of his professional life, as was eloquently affirmed at the funeral service by his pastor (the Rev. Idris Davies). W. E. Thomas set a high standard and leaves an influence of imperishable value in the mining valleys, and probably the best tribute to his memory would be to secure a real alleviation of the arduous life of a colliery practitioner by increased hospital and other services.

Dr. ALFRED COX writes:

I should be sorry if my old friend "W. E." were allowed to go without a salute from one who owed much to him in the way of kindness, hospitality, and enthusiastic co-operation in the work of the B.M.A. For many years he, with the late W. J. Greer, of Newport, was in the forefront of every battle at a time when South Wales was full of contract practice problems seemed too impulsive, Thomas was a born fighter. If he sometimes seemed too impulsive, he was a very astute politician and had many of the characteristics of his hero, Lloyd George. W. E.'s knowledge of the Welsh miners' leaders was extensive and peculiar. The B.M.A. could never be too grateful for his help in those critical times.

Centrally Thomas was also a prominent figure, and, as you truly said in your notice, "no Annual Meeting seemed complete without his genial presence." It was not that he spoke often. His work was done amongst the Welsh contingent, who had great confidence in his leadership. No picture of Thomas would be complete without some mention of his lively sense of humour, so I cannot refrain from relating one instance of it of which I was the victim, but a very appreciative one. W. E.'s colleagues in the Glamorganshire educational field presented him with his portrait, and I was invited to attend. I was unexpectedly called on to speak, and, while expressing my pleasure at being able to do honour to my old friend, I said that the artist (a lady, who was present) had missed what I thought was W. E.'s chief characteristic. She had portrayed a benevolent gentleman, a man in whom there was no guile, whereas we who knew him always thought of him as a born fighter, always "trailing his coat" and very sorry when no one accepted the challenge. This was very appreciatively received, but when W. E. got up to respond he said he had been maligned, and by the last person in the world who ought to talk about "loving a fight" for I, he said, was "the A. J. Cook of the medical profession." This brought down the house, for A. J. Cook was the most notorious militant, and almost vermillion in hue, of the miners' leaders at the time. Those who did not know the W. E. of twenty years ago must take it from seniors like A. T. Jones and myself that he was an outstanding figure, not only in B.M.A. circles but in nearly every branch of Welsh social and political life.

By the death on Feb. 6 of HUGH WANSEY BAYLY, M.C., aged 73, the medical profession has lost a colourful and many-sided personality. He was educated at Clare College, Cambridge, where he graduated as M.A. in 1898; and at St. George's Hospital, whence he qualified as M.R.C.S., L.R.C.P. in 1900. He was passionately devoted to the sea and to yachting, and spent some considerable time as surgeon on liners; quite early in this century he had the courage to operate on a case of perforated gastric ulcer on shipboard, having persuaded the captain to alter course so that he should be able to stand up while he did the operation; he was awarded for his pluck and skill by the recovery of his patient, and it was said at the time that this was the first such result on record at sea. Before this he had served with the Yeomanry in the South African Field Force in 1900-1. Later still he was in 1903 house-surgeon at Great Ormond Street Children's Hospital, after which he visited India. A serious attack of acute rheumatic pericarditis hindered his subsequent activities for a considerable time, but did not prevent him from serving as temporary surgeon in the R.N. in 1914-15, and in the R.A.M.C. in 1915-19 wherein he reached the rank of major. He had the melancholy duty of attending the late Raymond Asquith when he was fatally wounded in the trenches, and was himself wounded by a bullet which went right through his knee-joint without touching a bone; he was awarded the Military Cross for his services. Professionally he devoted many years of his career to the study and treatment of venereal diseases, and practised as a specialist in this branch of medicine in Harley Street. He wrote a textbook on syphilis, but did not obtain the unanimous assent of his colleagues to some of the views which he expounded. He was founder of the Society for the Prevention of Venereal Disease, of which he remained a vice-president up to his death. When the recent war began his fondness for the sea and his burning patriotism found an outlet in service as medical officer on a transport in 1939-40; but illness supervened and he was forced to retire into inactivity. It would be futile to claim that Bayly was a great clinician, but he was a man of inexhaustible energy and unbounded courage, both physical and moral. Last year he contributed to the *St. George's Hospital Gazette* a most entertaining (and instructive) account of the many exciting experiences in his adventurous life.

We regret to announce the death of Dr. VAUGHAN PENDRED, of Tilford, Surrey, which took place in hospital at Farnham on Feb. 1. He was born at Herne Hill in August, 1869, and was educated at Westminster School, at Newcastle-upon-Tyne, and at Guy's Hospital. He qualified in 1893, and after serving as obstetric resident and house-surgeon at Guy's graduated M.B. of Durham University with honours in 1896, and obtained the F.R.C.S. in the same year. He proceeded to the M.D. degree in 1901. Before entering general practice he worked as assistant in the throat and ear department of the Newcastle Infirmary and as assistant medical superintendent of Fulham Infirmary. He practised first at Buckingham, then at Coventry, and from 1913 to 1936 at East Sheen, after which he retired to live at Tilford. Dr. Vaughan Pendred joined the B.M.A. in 1897, was chairman of the Richmond Division in 1933-4, and represented it at the Annual Meeting of 1935. He had also been honorary secretary and vice-president of the West London Medico-Chirurgical Society.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Vice-Chancellor announces that the Rockefeller Foundation has agreed to make available a grant not exceeding £15,000 for research in neurophysiology under the direction of Prof. E. D. Adrian during the five years ending Jan. 31, 1951.

The titles of the degrees of M.B., B.Chir. were conferred by diploma on A. S. Willis of Newnham College in January.

UNIVERSITY OF LONDON

WESTMINSTER HOSPITAL MEDICAL SCHOOL

Two entrance scholarship examinations in anatomy and physiology will be held on March 13 and 14. Applications for further particulars must reach the Secretary, Westminster Hospital Medical School, 17, Horseferry Road, S.W.1, by March 4.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

Mr. R. Benesch, M.Sc., has been appointed to the British Drug Houses Fellowship for the study of the biochemical aspects of cancer, tenable at University College Hospital Medical School. He will work in the Department of Chemical Pathology under the direction of Prof. C. Rimington.

UNIVERSITY OF EDINBURGH

Prof. H. Davson, D.Sc., of Dalhousie University, will deliver a lecture on "Some Physicochemical Aspects of Vision" in the Biochemistry Lecture Room, University New Buildings, Edinburgh, on Thursday, Feb. 21, at 5 p.m. Students and graduates are invited to attend.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a meeting of the College held on Jan. 31, with the President, Lord Moran, in the chair, Dr. B. T. Parsons-Smith was re-elected the representative of the College on the Queen's Institute of District Nursing and Prof. J. W. McNee and Sir Arthur MacNalty on the Imperial Cancer Research Fund. Reports were received from the committee appointed to consider the training of general physicians, from the social and preventive medicine committee on student health, and from the committee on dermatology. All three reports were approved.

Membership

The following candidates, having satisfied the Censors' Board, were elected Members of the College:

H. W. Bunjé, M.B. Lond., Glenys M. M. Donaldson, M.B. Ed., H. H. Doss, M.B. Cairo, A. Erdei, M.D. Vienna, R. H. J. Fanthorpe, M.B. Lond., H. McC. Giles, M.B. Camb., C. H. Goldmann, M.D. Leipzig, Susanna Gordon, M.D. Chicago, H. N. W. Harley, M.B. Lond., W. E. Henley, M.B.E., D.M. Oxon., M. Hewitt, M.B. Lond., A. L. Humphrey, L.R.C.P., D. G. James, M.B. Camb., S. T. H. Jenkins, M.B. Lond., J. D. Judah, B.M. Oxon., J. J. Kempton, M.B. Bristol, Madeleine J. Mackenzie, M.B. Lond., T. N. Morgan, M.D. Aberd., L. Nancekivell, M.B. Lond., L. R. Patel, M.D. Bombay, M. G. Philpott, M.B. Lond., J. D. Roger, M.D. Toronto, R. Schneider, M.D. Berlin, J. C. Scott-Baker, M.B. Lond., J. C. Sloper, M.B. Camb., P. M. Smythe, M.B. Camb., C. J. Williams, M.B. Liverp., H. Wolfsohn, M.D. Lond., F. J. Zacharias, M.B. Liverp.

Licences

Licences to practise were granted to the following 159 candidates (including 27 women) who have passed the Final Examinations in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the necessary by-laws:

D. C. Adamson, R. W. Adlard, P. K. A. Andrews, E. H. Annels, D. A. Arthur, K. M. Backhouse, C. E. Bagg, R. I. W. Ballantine, D. A. N. Barran, A. J. Barry, J. B. Berry, A. V. G. Bibby, G. E. Bond, J. G. Briant, H. G. Broder, W. Brown, M. K. Bryce, K. Burchill, D. J. Burnett, G. H. Carrick, N. R. Chan-Pong, R. Clitherow, H. W. Colson, Olive Cooke, M. G. Cox, W. W. Cree, P. W. Dagger, D. G. Dalglish, P. W. Darby, W. H. Davies, H. R. De Vitre, E. Dillstone, Jean M. Druc, P. W. Durrans, Mary E. Eagles, S. Edelman, S. Eden, M. Evans, G. M. H. Evans, L. A. J. Evans, Elizabeth P. E. G. E. G. Featham, P. A. Feldman, M. R. Fell, A. T. R. W. Forrest, Frances A. Fouracres, J. M. Garratt, E. B. Gethen Smith, Jean M. Gilbert, M. J. Gilkes, J. Gloster, J. H. H. Glyn, Beryl M. Goetze, S. Goldwater, Janet Gordon, R. L. Greenwood, A. W. Halfhide, W. M. C. Halliman, R. J. C. Hart, P. M. R. Hemphill, N. D. H. Heneghan, A. C. Hill, Gina L. Hobbs, H. Hofstadter, B. H. Hogben, Vera Holdway, H. B. Houldsworth, J. D. Huntley, F. L. Jackson, Pauline M. Jackson, G. J. Jacobs, G. V. Jaffé, D. W. James, H. C. W. James, A. M. Johnson, A. T. Johnson, I. H. D. Johnston, G. F. Jolly, I. C. Jones, J. W. Jordan, W. P. Kelly, P. D. A. Kent, D. L. Kerr, S. J. Krister, Margaret A. Lakeman, C. H. B. Lawfield, Elizabeth J. Lee, K. Lowe, D. M. O. Lowry, H. A. R. Loxdale, Grace M. Lukose, Phyllis E. Lyne, N. J. C. McGill, H. W. Macintyre, E. W. F. Mack, Freda S. Mackover, I. K. R. McMillan, Sheila M. McNeile, A. E. Malone, F. M. Mann, B. Marsden, Martha H. Martin, R. F. Martin, C. G. W. Mason, J. D. Medhurst, D. McV. Merritt, R. H. B. Mills, W. I. Murdoch, D. Nuttall, R. H. Oldfield, T. C. L. Parry, R. A. J. Pearce, J. O. Pearce Edcumbe, R. M. Penny, P. P. Philip, Carol M. Plackett, R. M. Powell, R. D. Price, W. L. G. Quinlivan, O. T. Randell, S. S. Raphael, R. W. Rapinet, A. T. Richardson, J. H. Ridgwick, Yvonne H. H. Roberts, Calmen Rosen, C. T. Ross, Dorothy J. Roth, A. H. Saddler, R. St. Aubyn, D. V. Salkeld, Frances M. Saunders, R. E. Sidebotham, N. H. Silvertown, R. S. Smylie, K. A. Sowden, M. H. Stroud, W. K. Sutton, A. K. Thomas, R. H. Thomlinson, J. R. Tighe, H. W. Topham, D. A. H. Trythall, H. Wainstead, E. J. M. Weaver, Joan W. Wilkinson, J. D. Wilkinson, R. H. Wilkinson, J. R. B. Williams, R. D. Williams, C. J. Wilson, R. E. Woolley, G. R. Wotton, Sybil R. Yeates.

Diplomas

Diplomas in Anaesthetics were granted to the successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Jan. 5 (p. 34), and Diplomas in Laryngology and Otology and in Psychological Medicine to those whose names appear in the report of the meeting published in the *Journal* of Jan. 26 (p. 150).

Diplomas in Public Health and Medical Radio-diagnosis were granted, jointly with the Royal College of Surgeons of England, to the following successful candidates:

PUBLIC HEALTH.—J. Attard, Ada Barnett, J. E. Dickson, J. Fielding, T. H. Harrison, C. F. Ll. Hill, P. G. C. Jones, M. S. Moitra.
MEDICAL RADIO-DIAGNOSIS.—G. A. D. Gordon, P. F. Hauch, W. J. Latham, C. F. Parry, D. G. Wollin.

Medical Notes in Parliament

National Insurance Bill

Mr. JAMES GRIFFITHS on Feb. 6 moved the second reading of the *National Insurance Bill*. He said this was a culmination of half a century's development of British social services. The Bill consolidated into one the existing schemes of insurance against sickness, unemployment, and old age. It would bring economy in working and convenience to all concerned. These closely linked schemes would be under the control of a single Minister working through a single Department, and all the schemes would be based upon a single stamp upon a single card.

Sir HENRY MORRIS-JONES: Surely administration of health will remain under the Minister of Health.

Mr. GRIFFITHS said he referred to sickness benefit. All the people of this country would be brought under this all-embracing scheme. The sickness scheme was still not universal to-day. In sickness benefit the Bill raised the leading rate to 26s., compared with the present rate of 18s. for six months and 10s. 6d. afterwards. Grants to dependants were to be introduced for the first time in sickness benefits. The Government intended, in addition to giving cash benefits, to set up a comprehensive National Health Service, and to ensure that there should be the closest link between payment of cash benefits and provision of appropriate treatment. It had been estimated that the loss to the nation from preventable illness was £300,000,000 a year, equal to three-fifths of the total cost of this scheme in the initial year. He asked whether the nation could afford to go on without the scheme in view of the cost of preventable illness. Mr. Griffiths passed to the proposed maternity grant and allowance. He explained that a new allowance of 36s. a week for 13 weeks, 6 weeks before and 7 weeks after a birth, would only be paid if the mother stayed away from work.

Mr. R. A. BUTLER gave general support to the Bill, but calculated that the medical services, of which the House had not properly heard, would cost £105,000,000 yearly.

Sir HENRY MORRIS-JONES criticized the decision to defer or to refuse sickness benefit for 24 days in the case of self-employed persons. The only illnesses which lasted 24 days were seriously acute illnesses like pneumonia or chronic incurable diseases like cancer. Sir Henry remarked that the sickness ratio under the Bill was likely to be much increased. Many medical men told him that the ratio of illnesses of short duration had increased during the war. The position of medical men in dealing with sickness certificates was very difficult. The Minister might hope under the Bill and under the health scheme to have better control over the doctors in this matter, but Sir Henry warned him that he must not try to put the whole medical profession in a strait-jacket, or take away its freedom. If the Government did not get a friendly medical profession to co-operate with it the Bill would be damned.

The debate was resumed on Feb. 7 by Mr. ATTLEE, who said a comprehensive health service was yet to come. That service would be the Government's next instalment. He believed the benefits of the Bill and the provisions of the health service would save the immense loss which the country suffered through illness. Mr. LINDGREN offered favourable consideration in committee of amendments to allow sickness benefit for self-employed contributors to begin earlier.

The debate was again adjourned.

The Food Shortage

On Feb. 5 Sir BEN SMITH (Minister of Food) said the world's position in cereal supplies had deteriorated, and had been made worse by a series of droughts. All importing countries would have to make sacrifices. The British Government had accepted

a reduction of nearly 250,000 tons in United Kingdom wheat imports for the first half of 1946. This reduction could not be met out of stocks held in the country, it would have to be met by an early increase of the flour extraction rate to 80. That might not be the last step. The chance would be effected gradually. It could mean a return to the darker war-time loaf, but no deterioration in the nutritive value of the bread. It would reduce the volume of animal feed-stuffs with a consequent diminution of livestock production and less poultry, bacon, and eggs than the nation had hoped to enjoy later this year. The needs of the food-importing countries of the world were appalling. The world shortage of rice was contributory to the wheat shortage. Countries which could not secure rice turned to wheat or flour. The Government proposed not to issue rice to the civilian population of this country till world supplies became adequate. Owing to the shortage of cereals in India we should obtain less than half the quantity of ground nuts which we had expected from this source for vegetable oils. The whaling fleets sent to the Antarctic had had very poor results. Our stocks of oils and fats had been substantially reduced. He found it necessary to reduce the cooking fat ration by one ounce from March 3.

Mr. T. J. WILLIAMS announced on the same date that from May 1 pig and poultry rations would be based on one sixth of the pre-war stocks.

On Feb. 6 Mr. BEN SMITH answered eleven questions about the food and dried eggs. He said it was expected that during the spring of 1946 there would be a much larger supply of shell eggs than in 1945, and the Government had decided that it was not justified in bringing in as much dried egg as in 1945. There would be a gap in the allocation of dried egg during the period when shell eggs would be at their maximum. When the supply of shell eggs began to fall off the Ministry of Food would start issuing dried eggs again, but he could not say upon what scale.

Mr. HERBERT MORRISON announced on Feb. 9 that Feb. 14 would be devoted in the House of Commons to a debate on the world food shortage.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales infectious diseases were more prevalent during the week, and the following rises were recorded: measles 181, acute pneumonia 140, scarlet fever 89, whooping cough 78. The only large decrease was that of 50 for diphtheria.

Small increases in the notifications of scarlet fever were reported in most areas, the only notable exception being a decrease of 41 in Lancashire. London, with a decrease of 47, was the only exception to the general rising trend in whooping cough. The only large increases in measles were Norfolk 102, and Durham 35. Four counties—Norfolk, Suffolk, Lancashire, and London—contributed two thirds of the total measles notifications. The decrease in diphtheria was due to a few counties in London there were 20 fewer cases, in Warwickshire 14, in Yorks West Riding 13, and in Staffordshire 11, the only increase of note was Durham 17.

Typhoid has been reported from an institution in the Walhamstead district of London, the patients include two of the nursing staff.

Dysentery notifications were 13 fewer than in the preceding week. No further cases were reported from Peterborough where 38 cases were recorded last week. The outbreak in Leicestershire shows no signs of lessening, a further 139 cases were reported in this county during the week. The other large centres of infection were Yorks West Riding 58, London 33, Lancashire 26, Essex 13, Northumberland 13.

In Scotland in contrast with the experience of England and Wales, a fall was recorded in the incidence of most infectious diseases. The decreases included acute primary pneumonia 41, dysentery 24, diphtheria 8. Small rises were recorded for whooping cough and measles, of 19 and 11, respectively.

In Eire a further decline occurred in the incidence of diphtheria, the notifications of this disease having fallen by over one third during the past month. Cases of enteritis and diarrhoea rose from 9 to 22.

Week Ending February 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,351, whooping cough 1,265, diphtheria 496, measles 1,167, acute pneumonia 1,794, cerebrospinal fever 71, acute poliomyelitis 13, dysentery 407, paratyphoid 2, typhoid 7. During the week 297 deaths were attributed to influenza in the great towns.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 26.

Figures of Principal Notifiable Diseases for the week and the corresponding week last year for: (a) England and Wales (London included), (b) Scotland, (c) Eire, (d) Northern Ireland.

Figures of Births and Deaths for the week ended Jan. 26 for: (a) The 126 great towns in England and Wales (London included), (b) London (administrative area), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes data not available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative area), and Northern Ireland.

‡ Includes paratyphoid fever for England and Wales and Eire.

the hot weather, and as everyone does this it is very easy to conform to the custom. In such a case young children not only thrive but have a thoroughly healthy and enjoyable life.

The reason why a tropical country is not suitable for young children is that a hot, and especially a hot moist, climate tends to impair their vigour so that they may be less robust than children at home. Over and above this is the question of disease, especially malaria and intestinal diseases. Where conditions of life are likely to be civilized and comfortable, with good bungalows, fans, and other amenities, very young children, even if the climate is hot, would probably do quite well; but it would be unwise to take them to a tropical country without knowing what the conditions were going to be.

In the case of a young married couple it would certainly be a wise step for the wife and child to be left in England until the husband had had, say, six months' or a year's experience of the country. This would be an advantage in other respects, as he would be able to judge much better what conditions would be likely to be, and he would be in a better position to make things comfortable when his wife did come out. Short of this it would be a good thing to get in touch, if possible, with someone having local knowledge of the country, and to take his or her advice. An important matter which has to be considered is the long separation later when the children grow up. Life in the Tropics may have disadvantages, but it has a great many compensations, even for children, in the way of wider interests and experiences, and many pleasures that are not open to those who stay at home. Where a good opening offers some reasonable risk is well worth taking.

INCOME TAX

Income from Property

D. S. refers to an individual whose sole income is derived from the rents of property, and asks whether there is any way by which assessment under Schedule A can be avoided.

* Income from property is compulsorily assessed under Schedule A, with certain specific exceptions, which do not apply in this case—e.g., in the case of woods commercially managed. (Of the total tax (£25 approximately) payable for 1945–6, £9 15s. will ultimately be returnable as post-war credit.)

Whether Excessive Tax has been Deducted

"ANON." has been a surgeon lieutenant in the Navy since July, 1943, and has had tax deducted from his pay at from £11 5s. to £10 a month. Has he a claim to any refund?

* Prima facie the deductions have been excessive—on the figures given, to the extent of something less than £10 a year—but it is not possible to give advice without further details. We suggest that "Anon." should press the Income Tax Assessor's Department of the Admiralty for a detailed statement of his correct liability.

Replacement of Car

H. G. is in doubt as to whether to sell his present car and buy a new one. The car he has cost £200 in 1941, and he has had depreciation allowances on it amounting in all to £135 and bringing the written-down value to £65. If he now buys a new car he will receive a larger depreciation allowance in future. Does that make the transaction advisable?

* On the figures given H. G. would apparently become liable under the Income Tax Act, 1945, to a "balancing charge" of tax on £135, as the present car can be sold for over £200. That would nullify any advantage that the higher depreciation allowance on a new car would give him. Looked at purely from the income-tax standpoint it would seem good policy to continue using the present car (If the accounts of the practice are made up to Dec. 31 and the transaction were to go through now, the increased depreciation allowance would not be received until the year 1947–8, the tax on which is not due until January and July, 1948.)

Purchase of Debts

W. F. bought a practice including the outstanding book debts. In the event he has recovered a greater sum than the amount he paid for the debts. Is he liable for tax on the excess? (He is assessed on the "earnings" basis.)

* The point has not been decided in the Courts, and it is one on which there is much to be said on both sides of the argument. It seems to have hitherto been the usual practice for tax to be paid on any such excess, and for an allowance to be made to the purchaser for any deficiency. This is not inequitable, perhaps, and some practitioners would suffer if, when failing to recover as much as they had paid for the debts, they were refused any deduction for the deficiency—a result which would necessarily follow if an excess were held not to be taxable. On the whole we do not advise W. F. to carry the contention to appeal.

LETTERS, NOTES, ETC.

Microbial Antagonisms

Dr. GENNARO FUSCO, Medico Provinciale of the Naples Commune, writes: I have read in your number dated Dec. 22, 1945, a review on microbial antagonisms. It is right. For many years much has been written about it. But nobody has written about the antagonist substances that microbes make against themselves. For instance, if one tries to cultivate the plague bacillus on its own terrain of an old culture, growth is no more possible, but instead many other germs will grow. Is it not possible that this self-antagonism of a germ may have a practical and useful application in treatment and diagnosis?

A Case for Diagnosis

Capt. E. R. D. EASTMAN-NAGLE, S.A.M.C., writes from Rome: In reply to Fl. Lieut. G. A. Powell-Tuck's inquiry (Dec. 29, 1945, p. 950) I was myself "bitten" similarly on the hand while in the desert in Egypt in 1942, in similar circumstances. More detailed investigation revealed the point of a copying-ink pencil, presumably broken from that used by the local counterpart of the "dhobi" to mark the linen of his several clients with Arabic cyphers which he could interpret. Immediate expression of the point, and application of iodine, avoided the "secondary" infection which appears to have occurred in the original case, but the "blue" persists.

Efficiency of Ultra-violet Apparatus

Mr. J. W. KOLBERT (Hanovia, Ltd.) writes: The interesting paper by Fl. Lieut. B. C. Elliott (Dec. 22, 1945, p. 881) and your annotation (p. 890) discuss matters which, as you well say, should be known to every practitioner who employs ultra-violet light. In drawing conclusions from Fl. Lieut. Elliott's facts you have, however, omitted one item on which we should like to add a reassuring comment. We refer to the deterioration of lamps in use. Such depreciation of output is an inherent and marked feature of any and every quartz mercury arc, and while our own progressive efforts to reduce it have been not unsuccessful it is never negligible in amount. It is, however, obviated by the use of the "intensity stabilizer." Provided the user keeps a record of operating hours and duly uses the device he is relieved of all trouble due to deterioration.

Telephonic Delays

Dr. F. JOYCE (London, S.E.5) writes: I would like to draw attention to one glaring defect in the organization of many of the large voluntary hospitals, one conspicuous exception to this being the London Hospital. This defect is very old-standing and a source of irritation to all general practitioners. I refer to the procedure adopted when outside doctors ring up on the 'phone for admission of urgent cases. Usually the house-surgeon or the casualty officer on duty has to be fetched to answer the call and decide as to admission. The trouble is he is in some distant part of the building: it takes ever so long to locate him, and even then he may be engaged in operating or at some other critical occupation and cannot come immediately to the 'phone. Often, especially at night, one may be kept waiting from half to three-quarters of an hour. Surely something could be done to obviate this plague—for plague it is.

Toxic Effects of High Octane Petrol

Mrs. JEAN PATEY, F.R.C.S.Ed. (Handforth, near Manchester) writes: With reference to the question and answer on toxic effects of high octane petrol (Jan. 26, p. 152), is it not probable that the patient is suffering from "subacute" lead-poisoning? I believe that a proportion of high octane petrol contains lead. In view of the symptoms and signs ("pains in the back, epigastric fullness, gross hypertension, and severe retinitis") this should be borne in mind when carrying out further investigations.

Aged Blood Donors

Dr. N. J. C. RUTHERFORD (Farnham) writes: The modern method of bleeding to provide serum for hospitals during the war has, I am informed, become popular among people of advanced age. Having started the procedure on patriotic grounds, they found that the loss of blood benefited their health, consequently they continue the treatment by regularly attending blood transfusion centres. I heard recently of one lady aged 81 and another aged 72 who swear by the treatment. Apparently the age limit of 60 has gone by the board in competition between centres to keep up their supply figures. Should there be a limit?

New Year Honours

An omission from the New Year Honours list (Part II), published in the *Journal* of Jan. 19 (p. 100), has been brought to our notice. Cmdr. Thomas Henry Neville Whitehurst, M.R.C.S., L.R.C.P., Officer Commanding, No. 6 Ferry Pool, Air Transport Auxiliary, was appointed O.B.E. (Civil Division) "for services to aviation."

EXPULSION OF PATHOGENIC ORGANISMS FROM THE RESPIRATORY TRACT

BY

J. P. DUGUID, M.B., B.Sc.

(From the Department of Bacteriology, Edinburgh University)

The role of droplet spray in the transmission of infective diseases of the respiratory tract is not yet fully understood. Modern methods of observation have revealed that very large numbers of droplets are expelled during sneezing, coughing, and speaking, and that most of these are small enough to remain air-borne as "droplet nuclei" (Wells, 1935; Bourdillon, Lidwell, and Lovelock, 1942; Jennison, 1942; Duguid, 1945, 1946). Droplet nuclei (Wells, 1934) are the solid residues of those respiratory droplets which are small enough (less than about 100 microns in diameter) to evaporate completely before falling to the ground; after their formation they are capable of remaining air-borne for some minutes or for some hours, and of travelling long distances inside buildings. The demonstration that many such droplet nuclei are produced during expiratory activities has made it appear likely that air infection by droplet spray plays a part of major importance in the transmission of infection (see Wells and Wells, 1936). It has been found, however, by those who have investigated the expulsion of pathogenic organisms by infected persons that aerial infection is much more limited than is suggested by the purely physical studies of droplet spray, and that the pathogenic organisms of the respiratory tract (e.g., haemolytic streptococci and tubercle bacilli) are not expelled as readily or in as great numbers as the commensal organisms from a normal mouth or an indicator organism (e.g., *S. marcescens*) from an artificially infected mouth.

Bloomfield and Fely (1924), examining four patients with acute streptococcal tonsillitis, exposed blood-agar plates 3 to 12 in. (7.5 to 30 cm.) in front of the mouth during speaking, coughing, and sneezing for one-minute periods; droplets containing haemolytic streptococci were expelled by only one of the four patients, a few during coughing and a few during sneezing. In observations carried out in a similar manner during coughing by throat carriers, droplets containing haemolytic streptococci were found to be expelled in only 1 out of 9 tests on five carriers (Colebrook, 1933), and by only 1 out of 14 carriers (Paine, 1935). Hare (1940) examined 12 throat carriers of haemolytic streptococci, exposing five blood-agar plates in a quarter-circle in front of and below the mouth, at a distance of one foot from it; a few droplets containing haemolytic streptococci, comprising from 0.3 to 3.5% of the droplets recorded, were found to be expelled in 8 out of 37 tests of coughing six times in all, 11 infected droplets, and in 15 out of 47 tests of speaking or one minute (in all, 27 infected droplets). It appeared that the infected droplets were too large to remain air-borne as droplet nuclei; no droplet nuclei containing haemolytic streptococci were recovered by the Wells air-centrifuge from the air in front of the mouth in any of seven tests of speaking by five carriers. The production of some infected droplet nuclei during sneezing was demonstrated in subsequent tests (Hare, 1945). However, Hare does not believe that direct infection of the air with droplet nuclei plays any important part in the transmission of infection. He suggests that infection is spread through the air mainly by infected dust particles liberated from clothing, bedding, and room furnishings, after these have been soiled by the large infected droplets which fall out of the air within a few seconds of their emission. This view is supported by the findings of several investigators who have observed that numerous haemolytic streptococci may be present on the skin, clothes, and bedding of infected persons, and in the dust of rooms high they occupy, and also that these haemolytic streptococci are stirred up into the air in large numbers during sweeping, bed-making, and body movement (White, 1936; Brown and Allison,

1937; van den Ende, Lush, and Edward, 1940; Hare, 1941; Thomas and van den Ende, 1941; Thomas, 1941; Cruickshank, 1941; Wright, Cruickshank, and Gunn, 1944; Hamburger, Puck, Hamburger, and Johnson, 1944; Edward, 1944; Hamburger, Green, and Hamburger, 1945).

Tubercle Bacilli

The expulsion of tubercle bacilli during coughing by patients with open pulmonary tuberculosis has been demonstrated frequently; the infected droplets are caught on slides held in front of the mouth and are examined microscopically. Goldie (see Winslow and Robinson, 1910; Chapin, 1912) found that tubercle bacilli were expelled at one time or another by every patient examined, and on 14% of occasions when only a single cough was given. Ziesche (1907) made 61 examinations on 22 patients with open pulmonary tuberculosis, holding a 224-sq.-cm. glass plate 40 to 60 cm. in front of the mouth for 30 minutes during natural coughing; tubercle bacilli were expelled by 13% of the patients at the first examination and by 79% of the patients who were examined frequently; in 29 out of 61 tests tubercle bacilli were found on the exposed plate—less than 10 bacilli in three cases, between 10 and 100 in fifteen cases, between 100 and 1,000 in nine cases, 1,445 in one case, and 20,174 in one case. It appears that very few, if any, of the expelled droplets which contain tubercle bacilli are small enough to remain air-borne as droplet nuclei. Laschtschenko (1899) carried out five tests, in each of which a patient with open pulmonary tuberculosis, coughing naturally at intervals, sat in a small chamber for five hours while 10 cubic metres of air from the chamber were examined by filtration; air-borne tubercle bacilli were demonstrated in only two out of the five tests. Heymann (1931) carried out similar tests, each of one hour's duration; in most of these no air-borne tubercle bacilli were demonstrated, but on one occasion virulent tubercle bacilli were recovered from the air more than 30 minutes after the patient had left the chamber. The positive results obtained in these tests must be interpreted with caution, for they may as well have been due to infected dust particles liberated from the clothing of the patient as to infected droplet nuclei. Raising of infected dust seems the most likely cause of air infection, for tubercle bacilli have commonly been found in the dust of dwelling-places occupied by persons with open pulmonary tuberculosis (e.g., Cornet, 1899).

Organisms affecting the Respiratory Tract

Little appears to be known about the expulsion by infected persons of droplets containing such organisms as *C. diphtheriae*, *N. intracellulalis*, *H. influenzae*, *Dip. pneumoniae*, *Staph. aureus*, and the viruses of acute cornea, influenza, measles, smallpox, and other diseases affecting the respiratory tract (see Hare, 1945). There is, however, some evidence which suggests that certain of these pathogenic organisms may commonly be spread by infected dust. Crosbie and Wright (1941) found that virulent diphtheria bacilli were present in large numbers in the floor dust of diphtheria wards, that these bacilli remained viable in the dust for some months, and that they were stirred up into the air by sweeping; Avery and his colleagues (1917) and Sillman (1917) demonstrated the presence of viable pneumococci in room dust; and Edward (1941) showed that the influenza virus could remain viable in dust for some days or weeks.

In the absence of sufficient information, gained by direct observation, of the number of infected droplets which may be expelled by persons with such respiratory infections, it has been customary to assess the likelihood of infected droplet-spray production, and of subsequent air-borne infection, from the observed frequency of throat carriage of the pathogenic organisms concerned. During respiratory tract disease caused by infection with *Str. pyogenes*, *Dip. pneumoniae*, *C. diphtheriae*, *N. intracellulalis*, *H. influenzae*, and

Staph. aureus, or with certain viruses, the causal organisms are usually present, often in very large numbers, in the secretions of the tonsillar and nasopharyngeal regions. Moreover, apart from cases of actual disease, pathogenic organisms of many species may be carried in the throats of healthy persons—carriers—who form a considerable proportion, often from 1 to 10%, of the normal population. Droplet spray does not, however, originate readily from the tonsillar and nasopharyngeal regions. Jennison (1942), discussing the mechanism of droplet formation, argues that most droplets must originate from the secretions at the front of the mouth, except in the case of coughing with the mouth kept well open, when the zone of greatest droplet formation may be in the pharyngeal region. Photographic studies of droplet spray have shown that, in sneezing, droplets may be emitted from the nose as well as from the mouth; such nasal discharge is, however, usually much scantier than the oral discharge, more infrequent, and often made up of large masses of secretion rather than of discrete droplets (Bourdillon and Lidwell, 1941; Jennison, 1942). In a study (Duguid, 1945) of the numbers of droplets expelled during various expiratory activities the site of droplet origin was observed by use of an indicator organism, *S. marcescens*; it was found that most of the expelled droplets originated from the anterior mouth (about the lips, front teeth, and tip of tongue), and that only a few, perhaps between 0.01 and 1%, originated directly from the faucial region during coughing and sneezing, and from the nose during sneezing and normal breathing. Not many of these scanty nasal and faucial droplets were small enough to remain air-borne as droplet nuclei.

The production of air-borne infection with droplet nuclei must therefore depend mainly upon the presence of pathogenic organisms in the saliva of the anterior mouth. Faucial and nasal carriage may, on the other hand, be of much greater importance with regard to the production of air infection with infected dust particles: pathogenic organisms may be expelled from the nose or from the throat in masses of secretion or in large droplets and so give rise to infected dust. Bloomfield and Felty (1924) showed that, in contrast to the slight dissemination of infection in droplet spray, large numbers of haemolytic streptococci were emitted from the throat of an infected person in expectorated "hawkings." Recently Hamburger, Green, and Hamburger (1945) have shown that haemolytic streptococci are dispersed much more readily from the nose than from the throat. In an examination of 400 patients with haemolytic streptococcal infection of the upper respiratory tract it was found that about 80 times as many haemolytic streptococci were expelled on to the bedclothes by patients with strongly positive nasal cultures as by patients with positive throat cultures but negative nose cultures. The haemolytic streptococcal content of the air of a ward containing patients with positive nasal cultures was about 35 times as high as that of the air of a ward containing patients with only the throat cultures positive. Of 12 traced hospital cross-infections 11 originated from patients with positive nasal cultures.

It appears, then, that the danger of air-borne infection should be assessed not in terms of the occurrence of throat carriage of pathogenic organisms but in terms of the occurrence of oral carriage and nasal carriage. Moreover, infection of the nasal cavity and of the anterior mouth does not occur in regular association with infection of the throat. Pathogenic organisms may be disseminated forward from the throat during sneezing, coughing, hawking, and speaking, but the resulting infection is limited in duration by the action of eliminative mechanisms present in the mouth and in the healthy nose. Bloomfield (1921, 1922) showed that pathogenic organisms carried in the upper respiratory tract were for the most part confined to certain circumscribed localities, especially to the tonsils and pharynx; he described the presence in the mouth of a rapidly acting eliminative mechanism whereby bacteria are swept back to the pharynx in the salivary stream. Appleton and his colleagues (1938, 1944) found that the time required for the elimination of foreign organisms from the mouth varied (e.g., from 1/2 to 8 hours) with the numbers of organisms introduced, and that elimination was accelerated by increase of salivation. The removal of bacteria from the mouth appeared to be brought about mainly by the mechanical flushing action of the saliva and perhaps partly by a direct antibacterial action, ascribable to lysozyme activity, to sulphocyanate content, or to the antibiotic action of the normal salivary flora. An antibacterial action of the saliva has been described in the case of the diphtheria bacillus by Bézi (1932), by Dold and Weigmann (1935), and by Casassa (1937); in the case of the tubercle bacillus by Kanter and Appleton (1940); and in the case of the meningococcus by Gordon (1916). Elimination of bacteria from the nasal cavity appears to be effected similarly (in from 1/2 to 24 hours) by the backward current of the cilia-motivated mucus film and perhaps partly by a bactericidal action, as by lysozyme (Bloomfield, 1919; Arnold, Ostrom, and Singer, 1928).

Oral Carriage and Nasal Carriage

Few studies have been made of the oral carriage of pathogenic organisms; moreover, most of those published refer to the oral cavity as a whole and not to the anterior mouth alone; their

significance with regard to air infection is therefore difficult to assess. Oral carriage of haemolytic streptococci was found in 12% of examinations of healthy persons (Min. Hlth. Rep., 1930) and in 40 to 70% of examinations of throat carriers (Hare, 1940; Hamburger, 1944). Nasal carriage of haemolytic streptococci has been found with about one-quarter the frequency of throat carriage, in 0.05 to 5% of healthy persons (Min. Hlth. Rep., 1930, 1939; Peacock, Bigler, and Werner, 1939; Williams and Harper, 1944; Hamburger, Green, and Hamburger, 1945). Nasal infection has been found in from one-third to two-thirds of patients with acute streptococcal infection of the upper respiratory tract (De Waal, 1940; Hamburger, Green, and Hamburger, 1945).

Oral infection with diphtheria bacilli has been observed occasionally; a few published cases are quoted by Appleton (1944), and Reiche (1915) found labial lesions in 49 out of 7,314 fatal cases of diphtheria. The presence of diphtheria bacilli in the nose is much more common, occurring in healthy carriers, in cases of nasal diphtheria, and in a proportion of cases of faucial diphtheria: Boissard and Fry (1941, 1942) found diphtheria bacilli in nasal swabs from 19 out of 231 normal children examined at the time of an epidemic, and in nasal swabs from more than a third of 388 patients with faucial diphtheria.

Appleton (1944) has reviewed studies of the occurrence of tubercle bacilli in the mouth. Tuberculosis of the oral cavity has been found only rarely—in 127 out of 67,000 tuberculosis necropsies. Tubercle bacilli have been found frequently, however, in the mouths of patients with open pulmonary tuberculosis: for instance, in the mouths of 10 out of 20 patients by Gloyne (1922), and on the lips of patients by Gulbrandsen and Keller (1935).

The amount of infection disseminated in droplet spray is determined not only by the frequency of the occurrence of pathogenic organisms at the sites of droplet-spray formation but also by the numbers of these organisms present in the secretions at such places. Hamburger (1944), examining 554 samples of saliva from 156 persons with infected throats, found that the numbers of haemolytic streptococci in the different samples varied from 100 to 5,000,000 per millilitre, being in most cases between 1,000 and 1,000,000 per millilitre. On the basis of an observed droplet size-distribution, it has been calculated (Duguid, 1946) that of 5,000 droplets expelled by a cough only about 230 (4.6%) and 6 (0.1%) would be likely to contain pathogenic organisms when, respectively, 1,000,000 and 1,000 of these were present per millilitre of the secretions atomized. The number of infected droplets small enough to remain air-borne as droplet nuclei was calculated to be about 60 in the former case and 0 in the latter.

The present investigation was carried out in an effort to ascertain whether the expulsion of infected droplets depends upon the existence of pathogenic organisms in the secretions of the anterior mouth; this had appeared probable, as the great majority of droplets originate from the front of the mouth. Although the results of the investigation were to some extent inconclusive with regard to this question, it is considered that it may be of value to record them, for published observations of the expulsion of pathogenic organisms in droplet spray have been few and not very extensive.

Experimental

Three groups of infected persons were examined: 87 persons with haemolytic streptococci present in the throat, including 50 scarlet fever patients and 37 throat carriers; 50 faucial diphtheria patients with positive throat cultures; and 20 patients with pulmonary tuberculosis, in whose sputum tubercle bacilli had been demonstrated.

The mouth-spray droplets expelled by each person during a series of six voluntarily produced coughs were collected on a culture plate or microscope slide held about 3 in. (7.5 cm.) in front of the mouth. (Only the larger droplets would be collected by this method, which depends upon direct impingement. However, most of the pathogenic organisms expelled are contained in the large droplets. The majority of those expelled would be collected on the culture plate as these had an area (about 12 sq. in.: 77 sq. cm.) at least as great as the likely area of spread of the droplets at 3 in. (7.5 cm.) from the mouth. A smaller proportion would be collected on the microscope slides, which had only one-quarter of this area (3 sq. in.: 19 sq. cm.). Subsequent statements as to the numbers of infected droplets found to be expelled are subject to these limitations of technique.)

In the case of haemolytic streptococcal infections blood-agar plates were exposed; in the case of diphtheria, Hoyle tellurite plates; and in the case of pulmonary tuberculosis, microscope slides which had been warmed to prevent condensation from the breath obscuring the outlines of the droplet marks. After aerobic incubation for 48 hours the beta-haemolytic colonies on the blood-agar plates were counted; a separate count was also made of all the other colo-

present. Some of the beta-haemolytic colonies on each plate were subcultured in 5% serum broth and tested for soluble haemolysin production against sheep red cells; only those which produced soluble haemolysin were recorded as haemolytic streptococci. After incubation for 48 hours a count was made of these colonies on the Hoyle plates which had the appearance of diphtheria bacillus colonies; a separate count was also made of all the other colonies present. Some of the colonies on each plate were subcultured and their fermentation reactions tested; those which fermented glucose but not sucrose were recorded as diphtheria bacilli. The microscope slides which had been exposed to the coughing of the tuberculous patients were stained by the Ziehl-Neelsen method. Each slide was searched systematically for droplet marks under the low power of the microscope; the droplet marks were measured with the aid of a micrometer eyepiece and were searched for tubercle bacilli under oil immersion. The total number of droplets encountered on each slide, the number of droplets containing tubercle bacilli, and the number of tubercle bacilli in each droplet were recorded.

Before each test of coughing, and also after it for the tuberculous cases, swabs were taken from the throat (the surfaces of both tonsils and of the adjoining parts) and from the anterior mouth (the inner surfaces of the lips, the inner and outer surfaces of the front teeth and gums, and the tip of the tongue). In the examinations for haemolytic streptococci and diphtheria bacilli the swabs were plated on blood-agar plates and Hoyle plates respectively; the colonies were identified in the manner described for the cough-plate colonies, and their numbers were noted. In examinations for tubercle bacilli the swabs were first treated with acid by the method of Nassau (1941), and each was then rubbed on the surface of two Löwenstein egg-medium slopes; these slopes were examined at intervals during four weeks of incubation for growth of *M. tuberculosis* colonies, and the number of these colonies was noted.

Results

During a series of six coughs, droplets containing haemolytic streptococci were found to be expelled by 39 out of 87 persons with infected throats; between 1 and 10 infected droplets were expelled in 27 cases, between 10 and 100 in nine cases, and between 100 and 400 in the other three cases. In all, 1,109 infected droplets were expelled during 522 coughs—that is, about two infected droplets for each cough. As would be expected, the greatest numbers of infected droplets were generally expelled by the coughs which were the most forceful and which produced most droplet spray. Of all the droplets expelled by the 87 patients those containing haemolytic streptococci comprised only 10%. The proportion of droplets infected, however, varied greatly from case to case—between 0 and 80%. Haemolytic streptococci were found in the anterior-mouth secretions of 13 out of the 87 persons examined; the numbers of these were in six cases very small, in three cases moderate, and in only four cases comparable to the numbers found in the throat secretions. There was no apparent correlation between the expulsion of infected droplets and the presence of haemolytic streptococci in the anterior mouth. Infected droplets were expelled by 5 of the 13 patients with positive anterior-mouth cultures and by 34 of the 74 patients with negative anterior-mouth cultures; 63 infected and 720 non-infected droplets were expelled by the five patients with positive anterior-mouth cultures, and 1,046 infected and 7,500 non-infected droplets were expelled by the 34 patients with negative anterior-mouth cultures. This would suggest that some of the cough droplets, including most of the infected ones, must have originated directly from the throat. Such a conclusion, however, cannot be made with certainty, for it is possible that a few haemolytic streptococci were indeed present in the anterior-mouth secretions of those patients who gave negative anterior-mouth cultures, but that they were overgrown by the mouth commensal organisms in the heavily inoculated parts of the culture plates.

During a series of six coughs, droplets containing diphtheria bacilli were found to be expelled by 10 out of 50 patients with faucial diphtheria; only one infected droplet was expelled in five of these cases, two infected droplets in three cases, and, respectively, 10 and 27 infected droplets in the other two cases. In all, 48 infected droplets were expelled during 300 coughs—that is, about one infected droplet for every six coughs. The infected droplets comprised about 4% of all the droplets (which contained organisms cultivable on tellurite medium) found to be expelled by the 50 patients. Diphtheria bacilli were discovered in the anterior-mouth secretions of 12 out of the 50 patients; only very small numbers were present in 10 of these

patients and moderate numbers in the other two. There was no complete correlation between the expulsion of infected droplets and the presence of diphtheria bacilli in the anterior mouth. Infected droplets were expelled by 6 of the 12 patients with positive anterior-mouth cultures (in all, 43 infected droplets) and by 4 of the 38 patients with negative anterior-mouth cultures (in all, 5 infected droplets).

Droplets containing tubercle bacilli were found to be expelled during a series of six coughs by 10 out of 20 patients with open pulmonary tuberculosis. In all, 410 droplets were found on the slides exposed to 120 coughs; 36 of these droplets were infected, 19 containing between 1 and 10 tubercle bacilli, 9 containing between 10 and 100, 3 containing between 100 and 1,000, 4 containing between 5,000 and 20,000, and 1 containing about 40,000. The bacilli were packed so closely in the five most heavily infected droplets that only a rough estimate could be made of their numbers. All of these 5 droplets and 10 other infected droplets in addition were produced by one patient, who must have expelled at least 50,000 tubercle bacilli during the six coughs. Much smaller numbers were expelled by the other patients: one was found to expel 200 tubercle bacilli (in one droplet), a second to expel 175 (in nine infected droplets), a third to expel 60 (in one droplet), a fourth to expel 13 (in three droplets), a fifth to expel 6 (in three droplets), and the other four patients each to expel only one or two tubercle bacilli in a single droplet. The stain-marks of the infected droplets ranged from 30 to 3,000 microns in diameter, nine being under 100 microns. It is probable, therefore, that some of the infected droplets were small enough to remain air-borne as droplet nuclei. None of these small droplets, however, contained more than a very few tubercle bacilli. In the examinations made before coughing, tubercle bacilli were found to be present in the secretions of the throat of 15 out of the 20 patients, and in the secretions of the anterior mouth of 10 of the 20 patients; in two other patients infection of the anterior mouth appeared subsequent to the coughing. The tubercle bacilli were usually numerous in the throat secretions (e.g., a few dozen to a few hundred colonies being obtained on the slopes), and they were usually scanty in the anterior-mouth secretions (e.g., a few to a few dozen colonies being present on the slopes). A positive throat culture was obtained from all of the 10 patients who expelled infected droplets, and a positive anterior-mouth culture from eight of these. No evidence, therefore was obtained to suggest that infected material was atomized in the bronchi and expelled directly from there: formation of infected droplets probably occurred in the throat or in the anterior mouth, these localities having been soiled previously by sputum coughed up from the bronchi.

Summary

Droplets containing haemolytic streptococci were expelled during a series of six coughs by 39 out of 87 scarlet fever patients and throat carriers; 1,109 infected droplets were expelled during 522 coughs. Haemolytic streptococci, usually in small numbers, were found in the anterior-mouth secretions of 13 out of the 87 patients.

Droplets containing diphtheria bacilli were expelled during a series of six coughs by 10 out of 50 patients with faucial diphtheria; 48 infected droplets were expelled during 300 coughs. Diphtheria bacilli, usually in very small numbers, were found in the anterior-mouth secretions of 12 out of the 50 patients.

Droplets containing tubercle bacilli were expelled during a series of six coughs by 10 out of 20 patients with open pulmonary tuberculosis; out of 410 droplets collected during 120 coughs, 36 were found to contain tubercle bacilli in numbers varying from 1 to 40,000. Before coughing, tubercle bacilli were found in the throat secretions of 15 out of the 20 patients, and in the anterior-mouth secretions of 10 of the 20 patients.

I wish to thank Dr. A. Jee for permission to examine patients in the wards of the Edinburgh City Infectious Diseases Hospital.

PLASMA VISCOSITY: A CLINICAL TEST

BY

JOHN HARKNESS, M.B., B.Sc.
The Royal Asylum, Montrose

JOHN HOUSTON, M.B., D.P.H.
The Crossley Sanatorium, Frodsham
AND

R. B. WHITTINGTON, M.Sc.
The University, Manchester

While investigating the mechanics of blood sedimentation one of us (Whittington, 1942) found that if the maximum rate of fall of the cells is plotted against the plasma viscosity a complex pattern is formed. Under strictly controlled conditions this pattern is reproducible in any laboratory. Its somewhat bizarre appearance is shown by Fig. 1, which incorporates the results of our further investigations. Fig. 1 shows, moreover, that if the controlled E.S.R. is even a roughly proportionate index of a patient's pathological condition the plasma viscosity is not. And, of course, vice versa. From 63 cases of pulmonary tuberculosis Miller (Miller and Whittington, 1942) concluded that plasma viscosity was the more significant index. The 645 experiments reported here confirm this finding.

Method

Our technique is given in detail elsewhere (Houston, Harkness, and Whittington). Lack of space prohibits its full reproduction here. It is based on the use of a viscometer* which requires only 0.7 ml. of plasma and which is capable of an accuracy of about 99.8%. A water-bath, centrifuge, and stopwatch are the only other special pieces of apparatus required.

The viscosities quoted here are all "referred to Viscometer No. V5." Individual viscometers, if correctly calibrated, will agree in their results for pure liquids; but the apparent viscosity of a given colloidal solution will differ somewhat from instrument to instrument. Thus every viscometer will give its own

characteristic version of Fig. 1. This phenomenon may be made use of to standardize viscometers for plasma: the method is described elsewhere (Houston, Harkness, and Whittington).

A simpler scheme of standardization is as follows: any new viscometer, direct from the glass-blower, may be set up alongside V5 (which is still in existence) and a series of three plasmas (one normal, one medium, and one high-viscosity) run through both instruments. These three double tests provide in themselves enough data for the accurate calibration of the new instrument, which will give plasma viscosities "referred to V5" as in Fig. 1. Those investigators wishing to build up their own version of Fig. 1 for themselves will require to measure maximum sedimentation velocities in the manner described (Houston, Harkness, and Whittington).

Our results are given here for citrate plasma prepared by centrifuging a mixture of one part of 3.8% sodium citrate solution and four parts of venous blood. An empirical correction (Houston, Harkness, and Whittington) has been made for varying plasma dilution due to haematocrit variations.

Material

In all, 645 experiments were carried out; 223 were on cases of pulmonary tuberculosis at the Crossley Sanatorium, and 385 on patients with various pathological conditions encountered in Montrose Asylum (850 beds). These conditions included skin sepsis, gangrene, syphilis, malaria, paratyphoid, rheumatic fever, meningitis, pneumonia, pernicious anaemia, cerebral haemorrhage, carcinoma, and bone and pulmonary tuberculosis. In addition, 37 controls were drawn from radiologically and clinically normal members of the sanatorium staff and from psychotic patients who were physically normal.

Results

Space will not permit the reproduction of our results in detail. It is hoped that the four diagrams will summarize them effectively.

Fig. 1 was prepared by plotting simultaneous measurements of plasma viscosity and maximum sedimentation velocity (under strictly standardized conditions of cell volume, etc.). For convenience in considering the clinical aspect of our results the viscosity range (from roughly 1.4 to 2.1) has been arbitrarily divided into numbered zones by perpendiculars drawn from the "wave-peaks" as shown in Fig. 1. The 37 normal controls had a mean viscosity of 1.546. Of these, 30 (81%) fell in zones 1 to 3, the remainder falling in zone 4, with the highest at 1.626. There is, of course, no clearly defined boundary of normality, and zone 4 may be regarded as a threshold or transition range.

Fig. 2 shows the average viscosities corresponding to normal and Ministry of Health groups "minus," "plus 1," "plus 2," and "plus 3" in pulmonary tuberculosis. These cases were classified at the Crossley Sanatorium.

At Montrose, 177 tests in all were done on 79 patients giving viscosities in zone 6 or higher. These patients were suffering from various diseases. Using the maximum viscosity recorded for each patient, the accompanying Table gives the incidence of deaths among these high-viscosity cases.

Table showing Death Rate in Viscosity Zones

Viscosity Zone (V5)	Number of Cases	Deaths	
		No.	%
6	25	5	20
7	19	7	37
8	9	4	44
9	17	11	65
10	5	3	60
11	4	4	100
Totals	79	34	43

Discussion

(a) General

The conclusion to be drawn from Fig. 2 seems inescapable. At least in a chronic disease such as pulmonary tuberculosis there is an increase of viscosity corresponding on the whole to an increase in the extent and severity of the disease process.

* Supplied (to the design of R. B. W.) by the Scientific Glass-Blowing Company, 12-14, Wright Street, Manchester, 15.

FIG 1

Of course Fig 2 shows only average results. It would be absurd to claim, for example, that every tuberculous patient with a viscosity of 177 must necessarily fall into the Ministry of Health group plus 2. The diagram merely implies that if a large number of patients in group plus 2 be examined the average of their plasma viscosities will be about 177—referred to V5).

FIG 2—Distribution of Ministry of Health groups in pulmonary tuberculosis (223 cases + 37 controls)

But Fig 2 refers only to pulmonary tuberculosis from our experience in following the progress of both acute and chronic cases we are of the opinion that in general the viscosity increases

the viscosity to the right in Fig 1) as the pathological condition worsens and that with recovery the viscosity decreases again according to a shift to the left. In every complication or intercurrent infection may temporarily reverse the latter movement.

The grave prognosis in general to be associated with very high viscosities we feel, an inevitable conclusion to be drawn from the Table. That this, however, is only a generalization is shown by the fact that two patients with viscosity in zone 10 did eventually recover. (They were cases of paratyphoid and of rheumatic fever.)

We have mentioned that there is no clearly marked boundary between the normal and the pathological but that zone 4 may be regarded as a threshold range. Here fall the early and the late results of pathological processes together with some normals. The finding of a result in zone 4 appears to call for further investigation. This conclusion was brought home to us at Montrose, where two mental patients who were normal to physical examination and picked to act as normal controls gave results high in zone 4. Within six months the both developed definite signs of pulmonary tuberculosis. Further a member of the staff who gave a high zone 4 viscosity reading and who was at the same time clinically, radiologically, and bacteriologically negative developed active pulmonary tuberculosis within three months.

A zone 4 viscosity, then may be held to call for further investigation, but it need not occasion alarm. Seven of the Crossley staff controls were (low) in zone 4 and have as yet shown no signs of pathological disturbance. We have evidence that the use of the sulphamide drugs can produce an increase in the plasma viscosity sufficient to shift a physically normal zone 2/3 individual into zone 4. Other drugs may have a similar action. Moreover, we have as yet totally insufficient data as to physiological changes—e.g. menstruation—for do we know

to what extent a trifling infection (such as a common cold) may affect the viscosity.

A glance at Fig. 1 will confirm what we have said already—that viscosity and corrected sedimentation velocities cannot both be accurate indices: in our experience reliability is to be placed on the viscosity test, whatever the sedimentation result may be. Cases will be seen in Fig. 1 with extremely high viscosities but with sedimentation velocities falling within the range of normality. Case C202 is an interesting (though rare) example of the converse phenomenon, occurring in a clinically and radiologically normal female member of the sanatorium staff. Only five higher sedimentation velocities were ever recorded in our whole series. Viscosity was normal (zone 2/3). Repeated after 14 days, both velocity and viscosity results were practically identical. Observation of the sedimentation rate alone would have occasioned great alarm. Seven months after test C202, she is still perfectly healthy.

(b) Terminal Decay

Here we must describe an exception to the foregoing generalizations—a process which by its very exception may be of great importance to prognosis. So far we have in effect described a cycle of viscosity (normal—maximum—normal), a cycle which coincides with the clinical cycle (health—disease—recovery). But in many cases in which the disease process continues without respite to a fatal end the viscosity rises to a maximum value and then gradually falls towards the normal. In this way a value in the range of the normal may be reached in the moribund. We have called this phenomenon "terminal decay." In chronic conditions it may appear months before death, while in acute conditions it may precede death only by a few days or even a few hours. Some examples of this terminal phenomenon are shown in Fig. 3. We cannot state positively that this viscosity cycle (normal—maximum—normal) is invariably followed. It will be appreciated that the necessary evidence is not easily obtained from human subjects; but the general case is illustrated by the curves of Fig. 3.

Fig. 3.—Terminal decay. Chronic: M44, C11, C32 = pulmonary tuberculosis; M254 = pulmonary tuberculosis + mastitis. Acute: M140 = acute intestinal obstruction-carcinoma (colostomy 6 days before death); M334 = abdominal tumour (no p.m.).

Thus, before finally accepting any plasma-viscosity measurement as an indication of clinical condition, the possibility of decay must be considered. If this possibility is not out of the question the test should be repeated after a suitable interval. If the viscosity is increasing, decay is not present provided there is no intercurrent disturbance. If the viscosity is falling the plasma is either on the terminal path or is showing recovery. We feel that the clinician will easily decide this point. Sometimes, however, it is clear from a single viscosity reading that a patient is on the terminal path—for example, Case C50A, viscosity 1.576 (zone 3), 21 days before death from pulmonary tuberculosis. Here the viscosity result merely emphasized what was clinically all too obvious.

Fractionation of the plasma proteins is of distinct value in the recognition of terminal decay; but unfortunately any discussion of the serum and plasma proteins is beyond the scope of the present brief report.

(c) Plasma Viscosity and Management of Pleural Effusions

Fig. 4 shows the incidence of pleural effusions in 23 cases. There was definite clinical and radiological evidence pointing

to the actual formation of fluid at the time of test in each case. Fifteen (65%) were found to be in viscometric zone 7.

We consider Fig. 4 highly suggestive. It appears to indicate that zone 7 forms a critical region in which the exudation of fluid is highly probable. Of course our present small number of cases does not allow us to lay down definite limits beyond

Fig. 4.—Distribution of pleural effusions (23 cases).

which fluid cannot be exuded. But our experience indicates that if an effusion be aspirated while the viscosity is in zone 7 the fluid will re-form; recurrence is unusual when aspiration is delayed until the plasma viscosity has shifted either to the right or to the left. We have found, moreover, that a recovering patient sometimes has an effusion as his viscosity passes through zone 7 from right to left.

Viscosity measurements may thus prove of importance in the management of pleural effusions. (We hope to investigate this possibility further.)

Conclusions

Plasma viscosity can be of diagnostic value in revealing otherwise hidden pathological changes, as is emphasized in the Discussion (a). As a diagnostic test, however, it seems to be completely non-specific.

The prognostic value of the viscosity test appears to be high.

The viscosity test should be found valuable in the treatment of chronic disease, inasmuch as it provides a good index of deterioration or recovery.

Viscosity estimations may have special value in the management of pleural effusions.

A comparison of the sedimentation velocities in Fig. 1 with our findings for viscosity should show the impossibility of correlating sedimentation rates (even under controlled conditions) with the clinical picture.

These conclusions are drawn from 645 experiments on the plasma viscosity in a wide variety of pathological conditions.

We wish to thank our committees of the Royal Asylum, Montrose, and of the Crossley Sanatorium, Frodsham, for the facilities kindly afforded. Invaluable technical work was done by Miss Norah Brown and Mr. Archibald C. Harris.

At the annual meeting of the Governors of the Dental Hospital of Manchester it was announced that a department of preventive dentistry and research is to be created. Its work is to be linked with the school health services and maternity welfare centres, and with the new department of child health. Funds for the research to be undertaken have been provided by the Nuffield Trustees, who have made a grant of £30,000 spread over ten years. The University is also expected to provide financial assistance. The team of specialists will include an experimental physiologist, a bacteriologist, and two research fellows, together with the necessary laboratory and technical assistance and clerical staff. The intention is to launch a large-scale clinical study of the causation of dental disease.

NON-ABSORPTION OF MEPACRINE: DESCRIPTION OF A CASE

BY

JOHN YUDKIN, M.D., Ph.D., F.R.I.C.

In a paper published last year (Yudkin, 1945) I suggested that patients with malaria who do not respond well to oral mepacrine therapy might show a low urinary excretion of the drug. In such cases parenteral administration might be of value. Since then I have examined specimens of urine from hundreds of individuals on suppressive or therapeutic mepacrine and had not found one in whom there was a failure of absorption nor has it been reported by other workers. In August, 1945, however, such a case was seen in a West African military hospital. The patient was a young European naval rating with malaria who did not respond to large doses of mepacrine orally; he excreted only extremely small quantities of the drug in the urine and responded rapidly to a few small doses intramuscularly.

Case History

A stoker aged 20 was admitted to a naval sick bay on July 18, 1945, with "fever." Parasites of MT malaria were found in the blood and he was treated with quinine 10 gr (0.65 g) t.i.d.s for 5 days. He did not improve and was transferred to the military hospital on July 23. Examination of the blood revealed no malaria parasites, but he was still pyrexial, had rigors, was vomiting and complained of abdominal pain and headache. He was given a course of mepacrine as follows: 0.2 g four-hourly for 24 hours, 0.1 g four-hourly for 48 hours, and 0.1 g t.i.d.s for 48 hours—that is a total of 3 g in five days, in daily amounts of 1.2, 0.6, 0.6, 0.3 and 0.3 g. The patient was symptomless in four days, no parasites were present in the blood, and he was discharged fit on Aug 1.

On Aug 4 he reported again to the sick bay with pain and tenderness in his left foot. His temperature was 100°, and examination of the blood showed the presence of parasites of MT malaria. His foot was treated with local heat, and the condition subsided in three days. His malaria was treated with quinine 10 gr t.i.d.s for four days but again did not respond, and he was admitted to the military

hospital on Aug 8. On admission he complained of fever and malaise, his temperature was 104°, and his pulse 110. His spleen was palpable and malaria parasites (*P. falciparum*) were seen in the blood films. The same course of mepacrine was started at once. At the end of the fifth day, after 3 g of the drug, he was still pyrexial and his symptoms and general condition somewhat worse. He was given further large doses of oral mepacrine for four more days—1.2, 1.2, 0.3 and 0.3 g—t.i.d.s. Under the direct supervision of the senior medical officer, the patient's condition showed no signs of improvement and malaria parasites were still found on Aug 17. Examination of the blood on the day after admission showed a haemoglobin of 65% (Haldane) and a white cell count of 8,400. An attempt to improve the haemoglobin level was made by the administration of 100 mg of iron sulphate 2 t.i.d.s, but the haemoglobin was still 65% on Aug 18.

Urinary analysis between Aug 12 and 17 had demonstrated little or no mepacrine—less than 0.5 mg/litre—revels all other patients even had showed a concentration of 40–100 mg/litre after the first gramme of the drug.

On Aug 17 the tenth day in hospital, it was decided to use intramuscular mepacrine. A total of 0.9 g was given in divided doses—0.3 g at 2 p.m. and 0.2 g at 6 p.m. on Aug 17, 0.2 g at 6 a.m. on Aug 18, and 0.2 g at 10 a.m. on Aug 19. Within 26 hours of the first injection the patient was free from all symptoms and his temperature had fallen to 99°. Malaria parasites were completely absent from the blood from Aug 18 onwards. During the remainder of his stay in hospital his temperature never exceeded 99°. The spleen ceased to be palpable one week after the first injection. The haemoglobin responded slowly to the continued administration of iron in the same doses, and a level of 85% was reached by Aug 21.

An index of the level of mepacrine in the blood is given by the results of urinary analysis. One hour after the first injection the concentration rose to 0.2 mg/litre; one hour after the third injection it was 45 mg/litre and thereafter it began to fall. On Aug 22, when the concentration had fallen to 12 mg/litre, further oral mepacrine was begun and a total of 2.1 g was given over 5 days—0.3, 0.3, 0.3, 0.3, and 0.3 g. In spite of this the concentration of urinary mepacrine continued to fall steadily and reached zero on Sept 5. Before discharge I was decided to see whether the patient was able to absorb quinine. From Aug 28 he was given 5 g (0.42 g daily) all specimens of urine examined subsequently showed the presence of quinine by giving a positive Tartrated reaction. He was discharged from the hospital on Sep 6 and instructed to continue prophylactic quinine pending his return to the United Kingdom.

Discussion

Urinary specimens from very large numbers of individuals taking mepacrine by mouth have been examined, the numerous others in this field. No case has previously been described in which there was an almost complete failure to absorb the drug. The interesting features of the present case are the attack of malaria within two weeks of a previous attack, the lack of response to large doses of oral mepacrine, and the rapid response to relatively small doses of parenteral mepacrine. The absence of all but traces of urinary mepacrine during oral administration and the high concentration after parenteral administration, followed by the rapid clinical improvement, show that the absence of response to oral mepacrine was due to a failure of absorption from the alimentary canal. Another interesting feature was the failure to improve the haemoglobin level with iron until the malarial infection had been removed.

It is not clear why both attacks of malaria did not respond to oral quinine. It is possible that the patient did not absorb quinine during the malarial process, although he was able to do so after he had been cured. The inability to absorb oral mepacrine, however, persisted after his cure. The fact that the second attack of malaria occurred within three days after being discharged from hospital following his first attack shows that this attack, too, had not been cured by oral mepacrine.

Summary

A case of MT malaria in a European in West Africa which failed to respond to intensive therapy with oral mepacrine is described. Urinary analysis showed that the patient was not absorbing the drug. Subsequent administration of mepacrine intramuscularly resulted in a rapid recovery.

I have to thank Col. A. J. Leslie-Spinks, commanding officer, and Lieut. Col. A. S. Hollins, officer in charge of a Medical Division, for permission to publish this case. I am especially grateful to Capt. P. U. Colver, medical specialist, for his keen co-operation and his generous clinical advice.

THE CEPHALIN FLOCCULATION TEST IN
MALARIA

BY
JACK G. MAKARI, B.A., M.D.
(From the Department of Bacteriology, American University of Beirut)

Since the cephalin-cholesterol flocculation test was first described by Hanger in 1938 it has been applied almost entirely to the study of diseases of the liver parenchyma, especially to jaundice and cirrhosis. Hanger (1939) used the test in the differentiation of obstructive from hepatogenous jaundice. These findings were confirmed by Nadler and Butler in 1942. Hanger and Patek in 1941 correlated the results of the test and the clinical course of 40 patients with liver cirrhosis. In 1942 Mateer and his co-workers made a very thorough comparative study of the newer liver function tests and came to the conclusion that the cephalin flocculation test is one of the three best hepatic function tests recommended for routine use.

The clinical investigators who have made extensive use of the cephalin-cholesterol flocculation test seem to agree that: (1) the test is negative in normal individuals; (2) it is a more sensitive indicator of active disturbance of the liver parenchyma than any of the so-called liver function tests; (3) it provides the best available indicator as to prognosis in hepatic disease. I have been unable to find in the literature any mention of the use of this test as an index of "insult" done to the liver by infectious processes.*

The purpose of this paper is to report my findings on the behaviour of the cephalin flocculation test in malaria, with consideration of the possible use of the test as an index of the activity of malaria parasites in the tissues of the host.

The cephalin† used was prepared according to the method described by Hanger (1938). The preparation of the testing emulsion and the method of reading and recording the results of the tests conformed with Hanger's original procedure. The cases studied consist of three groups: (1) cases of malaria collected from Anjar‡; (2) cases of malaria observed in the wards of the American University Hospitals; and (3) cases in which malaria and liver disease were ruled out.

Group 1: Cases of Malaria Collected from Anjar

The sera of 92 cases were studied in individuals varying from 4 to 80 years of age. The duration of symptoms varied from 2 weeks to 3 years. In each case we obtained: (1) a short clinical history; (2) the size of the liver and the splenic index in centimetres; (3) blood smears for malaria; (4) blood for the cephalin flocculation test. Only two cases which had no history of chills, fever, splenic enlargement, or other signs of malaria could be included as controls. In both, smears for malaria and cephalin flocculation tests were negative.

Results.—Of the 92 persons with a positive history 83 had a positive cephalin flocculation reaction—80 of these being ++ and above—and 65 had positive smears. Of the 9 cases with a negative cephalin flocculation reaction 4 had negative smears,

4 had *Plasmodium falciparum* infection, and only one had *Plasmodium vivax* parasites in the blood smear. There seems to be no definite correlation between sex, age, duration, last

Table showing Distribution of Cephalin Flocculation Reactions in 92 Cases of Malaria from Anjar. (Group 1.)

Cephalin Flocculation Test:	0	±	+	++	+++	++++	Total
P. vivax	1	—	—	1	4	8	14
P. falciparum	4	1	—	—	3	15	23
P. vivax and P. falciparum	—	—	—	—	1	2	3
Questionable rings	—	—	—	2	2	19	23
Neg. smear but positive history	4	1	1	5	3	15	29
Total	9	2	1	8	13	59	92

attack in days, splenic enlargement, and the cephalin flocculation test. The correlation between the clinical diagnosis, the cephalin flocculation test, and positive blood films is shown in Fig. 1.

FIG. 1.—Correlation between clinical diagnosis, the cephalin flocculation test, and positive blood films in 105 cases of malaria.

On the basis of the above data we conclude that in malaria the cephalin flocculation reaction is predominantly positive and may be strongly so.

Group 2: Cases of Malaria Observed in the A.U.B. Hospital

This group consists of 13 subjects varying from 14 to 67 years of age. In addition to the procedures followed in Group 1, these cases had their cephalin flocculation tests repeated with a view to finding the response of the test to antimalarial treatment.

Results.—In all of these cases except one the cephalin flocculation reaction was strongly positive on admission (++++ and above), and came down to + or negative after antimalarial treatment was administered (Fig. 2). In the one exception which

FIG. 2.—Behaviour of the cephalin flocculation test in a case showing satisfactory response to therapy.

* After this paper was written Mirskey and co-workers reported on the test being positive in ten cases of malaria. This preliminary report, entitled "Hepatic Dysfunction in Malaria," was published in *Science*, 1944, 99, 20. They noted that patients treated with a high-carbohydrate high-protein high-vitamin diet showed a rapid disappearance of the positive cephalin reactions, while patients not treated in this manner showed a positive reaction for as long as one year after the last attack. Group 2 in my series were not treated in the manner those authors describe; in fact, these patients received ordinary ward diets, and yet their reactions became negative within a period of about two weeks from the start of antimalarial treatment.

† The cephalin used was prepared in the Department of Biochemistry of the American University of Beirut.

‡ Anjar is an Armenian refugee village situated in the Bekaa Valley, on the outskirts of the Anti-Lebanon Mountains, on the Damascus road 15 km. from Chitaura. It is one of the worst-infested malarious districts in Syria and the Lebanon.

showed a tendency to relapse despite intensive antimalarial treatment given thrice in the hospital, the cephalin reaction remained consistently +++ even when the patient no longer had symptoms of malaria and was readmitted to the E.E.N.T. Service for ulcerative keratitis. I have used the test on cerebrospinal fluid in two cases with cerebral malaria and coma and found i

to be —. The cephalin flocculation test done on the blood of these two cases was —+ in one case and +++ in the other. Blood smears showed the presence of *P. falciparum* in both cases. In a case of chronic malaria with splenomegaly the cephalin flocculation test on the splenic blood was —, while on the peripheral blood it was —+—, despite the fact that no malarial parasites could be demonstrated from either the splenic puncture material or the peripheral blood.

On the basis of the above data it seems reasonable to conclude that the cephalin flocculation test is an index of malarial activity in the tissues of the host.

Group 3 Cases in which Malaria and Liver Disease were Ruled Out (Controls)

This group of 90 cases consisted of subjects observed in the AUB Hospital wards, and may be considered as a group of controls.

Results In all cases the cephalin flocculation test was negative.

Discussion

In a paper I have presented evidence that in the great majority of malarial cases the cephalin flocculation test is positive to a significant degree. The percentage of positive tests was greater than the percentage of positive smears in our series. The fact that the test became positive near the onset of clinically recognizable symptoms should facilitate an early diagnosis of malaria where infectious hepatitis is ruled out, even though splenic enlargement may not be noted and blood films may still be negative for plasmodia.

I suggest that the cephalin-cholesterol flocculation test be carried out as a routine on all prospective blood bank donors, and that all positive reactors be excluded as possible carriers of malaria or infectious hepatitis. The need for the application of such a procedure to persons who have been in high malarious areas, particularly returning personnel of the Armed Services is obvious. The simplicity, reliability and established significance of this test in infectious hepatitis and chronic malaria make it the obvious method of choice for routine use.

Summary

The cephalin flocculation test was done on sera obtained from 105 malarial cases. A positive flocculation reaction was obtained in 96 cases (91.4%) it being ++ and above in 94 cases (89.5%). The proportion of positive smears was 73.7% (77 cases).

The cephalin flocculation test tended to become negative with anti-malarial treatment. It thus may be used safely as an index of the activity of malarial parasites in the host.

Use of the test on cerebrospinal fluid is suggested in cerebral malaria to determine the degree of activity of the infection.

Routine use of the cephalin test on all prospective blood bank donors is also suggested.

I am indebted to Dean G. H. Miller, Professor of Internal Medicine, Drs. E. W. Dennis, Professor of Bacteriology, and S. E. Kerr, Professor of Biochemistry, of the School of Medicine of the American University of Beirut, for their encouragement and valuable suggestions, and to Miss A. Der Boghossian and Mr. K. Seradainian for their technical assistance. I also wish to thank Professors H. Yem Komshian, G. Khayat, and C. Baylor, of the Department of Internal Medicine, AUB Hospital, for permission to include their cases in this paper.

SOME PAEDIATRIC PROBLEMS PRESENTED AT BELSEN CAMP

BY

W. R. F. COLLIS, M.D., F.R.C.P., D.P.H.

Senior Medical Officer British Red Cross Commission for Children
 Peleef Belsen Camp

AND

P. C. MacCLANCY, L.R.C.P.S.I.

Medical Officer British Red Cross Society Belsen Camp

Looking through the case records from the paediatric department in the Belsen Hospital three cases seem worthy of permanent record.

Case I

A Czech girl aged 14 was found somewhere in the forest area in a very bad condition with the diagnosis of "heart disease". She was removed to the children's hospital and her case was followed up as fully as possible. She had a past history of typhus in the horror camp. Before admission to the children's hospital her mother on her case stated that she had been suffering from diarrhoea and had shown some oedema. For the last 48 hours she had received injections of nicotinic acid and calcium, and sulphate hazo-bis-methyl. She was rather big for her given age (probably more than 14 years), was much emaciated, and appeared conscious, of her current illness unusually apathetic. Temperature 99-102° F., pulse 120.

On examination cardiac dullness was found to extend some 2 in (5.3 cm) outside the left nipple line and 1½ in (3.8 cm) to the right of the sternum and above the third rib. There was no visible pulsation. The heart sounds were normal, no murmurs. There was a cough with a little sputum. Moist sounds were heard all over the chest, most pronounced on the left side. C.N.S. Reflexes were decreased on admission. The abdomen was thin but no tenderness was manifested there. No oedema was present. The lungs were normal. Radio has revealed considerable enlargement of the heart shadow both in size and soft generalized shadows in both areas. The appearance suggests dilatation seen in initial stages of malarial infection and the clinical condition is compatible with pulmonary congestion (see Fig. 1). The blood sedimentation rate for the

FIG 1—Skiagram of Case I, June 1, 1946

first hour was 144 mm (Westergren), blood urea, 12 mg/100 ccm plasma protein, 6.5 mg/100 ccm, haematocrit, 26, colour index, 0.9, haemoglobin, 45%, red blood cells, 2,960,000, white blood cells, 5,800 (polymorphs 62%, lymphocytes 38%), erythrocytic normochromic anaemia, iron deficiency.

After discussion pericarditis was considered to be the most probable diagnosis, taking into account the temperature, the size of the heart, and the lack of murmurs. Aspiration of the pericardium was attempted the posterior route being chosen. The needle was

* Blood examinations carried out by Capt. P. L. Molesworth.

The Minister of Health has made an Order under Section 2 of the Water Act, 1945, dealing with the constitution of the new statutory Central Advisory Water Committee, which will be set up in due course. The Order follows the lines of that for the Central Housing Advisory Committee, by providing that the Minister himself shall be in the chair and the Parliamentary Secretary will be the vice-chairman. The committee will have twenty other members and, like the previous non-statutory committee under the chairman ship of Lord Milne, will represent all the interests concerned with water supply matters. Members will be appointed for four years with 50% retirement every two years.

pushed slowly as far as the heart muscle and slowly withdrawn, but only a few drops of blood entered the syringe.

We considered the matter again in the light of this finding, and felt that the most likely diagnosis was still pericarditis, probably tuberculous, with pus too thick to pass through the needle. The possibility of a pure dilatation due to vitamin B deficiency was also considered, and the child was given a diet rich in vitamin B₁ and later injections of thiamine hydrochloride. The nicotinic acid injections were also continued. Within a week the child's appearance had quite altered. Her temperature fell to normal; she ceased to be apathetic, but remained unresponsive and somewhat hostile, though by this time all the other children in the beds around her had lost their terror symptoms. Later the temperature rose again, though not to the same height as before, but her clinical improvement was continuous. We now decided to include her among the cases for evacuation to Sweden. (Previously her condition had seemed too bad to warrant this.) She stood the journey well and was admitted to the Lung Clinic in Malmö. Here she was x-rayed again exactly one month after the previous film. The heart (Fig. 2)

FIG 2—Skiagram of Case I, July 23, 1945.

had now come in completely; the skiagram shows, however, a considerable degree of pulmonary tuberculosis, accounting for the temperature.

One of us (W. R. F. C.) took the skiagrams to Stockholm, where he discussed the case with Prof. A. Wallgren and others. Prof. Wallgren felt that the diagnosis rested between a pure dilatation of the heart—probably of the B₁-deficiency type—or a serous effusion which had cleared up. He showed a case of the latter from his records. The general opinion leaned towards the diagnosis of a beriberi heart.

Comment on Case I

Other observers (Collis, 1945; Lipscomb, 1945; Vaughan *et al.*, 1945; Mollison, 1946) at Belsen have said that frank vitamin deficiency syndromes were rare among the adult population. Among the children we saw no case of vitamin A deficiency or scurvy, nor did we observe any case of active radiological rickets. Tetany was not uncommon, however, and many cases were undoubtedly suffering from a derangement of the calcium-phosphorus balance. Lack of facilities made it impossible for us to investigate the blood calcium, phosphorus, and phosphatase. Vitamin B deficiency (both B₁ and B₂) was, however, not uncommon. Although we did not see textbook cases of beriberi or pellagra, many of the children had lost their reflexes and had defective balance; others showed a non-infective type of diarrhoea which improved with nicotinic acid. They also showed stomatitis, glossitis, and marked pigmentation of exposed parts of the skin. Hence it is not improbable that the above case is a true beriberi heart.

Case II

This case will be of interest because of its association with tuberculous allergy and the aetiology of erythema nodosum. L. G., a boy aged 9, while in hospital suffering from a slight cold was tuberculin-tested as a routine, with a negative result. Six days later the temperature rose sharply and continued to climb, reaching 103° F. in five days. On the second day of the fever the typical red raised eruptions of erythema nodosum appeared on the extensor surfaces

of the legs. The following day he was again tuberculin-tested, and the reaction had now become positive. His skiagram showed a typical early primary lesion around the hilus of each lung, spreading out into the parenchyma, particularly on the right side. The sedimentation rate was 120 mm. (first hour Westergren).

This case shows the classical picture of the primary tuberculous state in a heavily infected child with a rapidly developing high allergy and erythema nodosum.

Comment on Case II

After the typhus, starvation, and fear syndromes had been overcome the final clinical problem among the children was tuberculosis. We calculated that typhus combined with starvation had reactivated over 1,000 cases of pulmonary tuberculosis in the camp. Hence it was not surprising that a very high percentage of the children were infected. In a survey carried out by one of us (P. C. M., assisted by M. John Moerman, Ghent Medical School) 80% of the children were found to be Pirquet-positive (average age in group, 7.1 years).

Every phase of the disease was observed. We saw children, as above, at the beginning of their allergic response, in the primary complex, others healing, and others healed. There was a group of about ten showing secondary generalized spread (miliary tuberculosis, caseous bronchopneumonia, and tuberculous meningitis), and seven cases of the adult type of phthisis in children aged from 9 to 15.

It will be of interest to many to hear that the Swedish Red Cross took all but the dying patients to Sweden, where already all the primary cases are well on their way to recovery and most of the tertiary (adult type) are greatly improved.

Sedimentation Rate.—Mollison (1946) observed that the sedimentation rate was greatly increased in starvation states at Belsen, and that its return to normal took usually some two months. We carried out the sedimentation test in over 100 children, and repeated it on several subsequent occasions in many. Starvation alone seldom produced a sedimentation rate of over 50 mm. for the first hour. But when combined with the post-typhus state and tuberculosis the most surprising results were recorded, as in the cases above. The record was 147 mm. in the first hour (Westergren). In spite of this, however, we found the test of very great value in assessing the degree of activity to tuberculosis and the progress of our cases generally when repeated at regular intervals.

Case III

A boy, Z. Z., aged 5, was admitted to the children's hospital, Belsen, from the general hospital on the death of his mother. His mother, an Austrian Catholic, died at Belsen of typhus. The father, a Slovak Jew, last heard of in Sachsenhausen, was probably dead. A sister, aged 6, was alive and well in camp. Two other children died in Ravensbruck lager. Nothing was known of the patient's past history.

On admission he was very emaciated. He lay rolled up in a ball under the bedclothes, moaning, and wouldn't eat or speak. Examination revealed pleurisy with an effusion on the right side, and some infiltration in the right and the upper zone of the left lung. The temperature was irregular, rising to 101°. Sedimentation rate, 101 mm. first hour (Westergren). Pirquet plus. 10 c.cm. of serous fluid was aspirated to exclude empyema.

The child was hand-fed with specially appetizing meals while being talked to in his own language. He was given a high-protein diet with an addition of vitamins and calcium, and at first was kept in a warm room; later he was placed in the open air. After one week he began to talk; after two weeks his appetite returned; and after eight weeks the sedimentation rate was 50 mm. He was then evacuated to Sweden. The latest report states that he has put on 7 lb. (3.2 kg.) and is now almost well.

Comment on Case III

The above case illustrates the final problem of the Belsen children. It is a social one of the most profound complexity. Here we have a little boy of 5, together with his sister of 6, whose parents have been cruelly murdered and whose family and home have been destroyed. What is to become of him? Is he to be brought up Jew or Catholic? Is he to be left in an orphanage? He has found a temporary refuge in Sweden, but what of the future?

The work reported above was greatly assisted by M. John Moerman and other members of the Shaf Medical (Belgian) Mission. Our thanks are due to the senior medical officers and officers

Summary

The literature concerning "spontaneous rupture of the liver" has been reviewed briefly, and particular attention has been drawn to the only case on record of spontaneous rupture complicating pregnancy. A further case is here described, and it is interesting that both have terminated successfully. The aetiology in the present case is very obscure, but it is suggested that the rupture may have been caused by a sudden hypertension. Spontaneous rupture of the liver should be borne in mind when seeking a cause for intraperitoneal haemorrhage of hidden origin.

I wish to extend my thanks to Mr. J. Gaymer Jones and Mr. D. Maxwell for their permission to publish this case.

Medical Memoranda

Unusual Sequel of a Large Overdose of Insulin

The following case of prolonged and profound hypoglycaemic coma seems worth recording on account of the following features: (1) the huge dose of insulin; (2) the prolonged hypoglycaemia in spite of large doses of glucose; (3) the persistence of mental symptoms for a considerable time after the correction of the blood sugar, and the subsequent complete recovery of normal mental function.

CASE HISTORY

A man aged 25, a known diabetic for 13 years, was recently stabilized on 30 units of soluble insulin twice daily and a diet of 240 g. of carbohydrate. In the 1940 air raids he was badly concussed, and has since been treated at the Maudsley Hospital for depression and "mental absences."

On the evening of July 7, 1945, he took his usual dose of insulin and his supper. He went out, returning at 10 p.m. rather quieter and more depressed than usual. An hour later he told his mother that he had taken a very large dose of insulin for no known reason. It was found that he had emptied a 10-c.c.m. ampoule of 80 units per c.c.m. soluble insulin which had been in use only 3 days, and it may be presumed, therefore, that he had taken a large part of the 560 units remaining in the ampoule. His mother said that he then took 3/4 lb. (340 g.) of sugar by mouth and returned to bed. Next day at 6 a.m. he could not be roused, and 1½ hours later he was admitted to King's College Hospital in hypoglycaemic coma. On examination he was found to be deeply comatose, flaccid, and sweating profusely. The pulse was slow and bounding, rate 52, and the blood pressure 130/80. All deep reflexes were absent. He was given 30 g. of glucose intravenously, and immediately became rigid, started shouting, and was difficult to control. A further 20 g. of intravenous glucose was given, and he became just able to drink, though irrational and noisy. An hour later the blood sugar was found to be 45 mg. per 100 c.c.m., so more glucose was given by mouth, and the patient seemed quieter though still mentally confused. At noon he became drowsy again, and a further 20 g. of glucose was given intravenously and more by mouth. However, the latter was almost immediately vomited together with undigested food from supper the previous night. Half an hour afterwards his blood sugar was 34 mg. per 100 c.c.m. in spite of the 70 g. of glucose so far given intravenously. It is interesting to note the continued fall in blood sugar in spite of the large and repeated doses of glucose.

The patient's general condition was still deteriorating, so 5% glucose-saline was given intravenously, and by 6 p.m., after 2 litres (= 100 g. glucose), the blood sugar was 210 mg. per 100 c.c.m. In spite of this raised blood sugar the patient remained confused and restless, and became violent and maniacal on the slightest stimulus. Morphine 1/4 gr. (16 mg.) and other sedatives, such as paraldehyde and hyoscine, were given four-hourly throughout the night without good effect. At 2 a.m. the intravenous glucose-saline was discontinued after 5 litres of fluid had been given, and after a stomach wash-out the patient was able to retain sugar drinks by mouth. His carbohydrate intake was then adjusted by mouth, and small doses of insulin were given to prevent ketosis. In spite of normal diabetic control, the patient's mental condition was completely unchanged. With 6 gr. (0.4 g.) of sodium gardenal he slept throughout the morning of July 9, and at noon his blood sugar was 190 mg. per 100 c.c.m. He continued in a deep sleep until early afternoon, and then awoke very drowsy but mentally clear and orientated. He had complete amnesia for the whole incident since supper-time on July 7. He made an uneventful recovery and was seen again a fortnight later at the Maudsley Hospital, where little change in his mental state was reported.

I wish to thank Dr. R. D. Lawrence for his help in preparing this paper.

 King's College Hospital.

Reviews

HISTORY OF MALARIA IN AMERICA

Malaria in the Upper Mississippi Valley, 1760-1900. By Erwin H. Ackerknecht. (Pp. 142. \$2.00.) Baltimore: The Johns Hopkins Press. 1945.

It has always been difficult to correlate the facts about malaria prevalence in America with the epidemiological features of this disease in the Old World. The reason is easy to appreciate, for malaria in the New World is not an age-long established disease in indigenous races as it is almost everywhere in the Old World, but one associated with the unique conditions of a continent peopled within a few hundred years by white pioneer settlers and their descendants. We know nothing about what the conditions were before this settling, even whether malaria existed at all, and, except for the efforts of a few writers to probe into the darkness, very little about malaria during the early years of American occupation. A recently published rather remarkable monograph entitled *Malaria in the Upper Mississippi Valley, 1769-1900*, by E. H. Ackerknecht of the Johns Hopkins Institute of the History of Medicine, is therefore of unusual interest, since it is a record of a very complete and exhaustive investigation of this whole subject. Not only does it give the story of malaria in America in a more complete form than has ever been done before, but as an epic of the history of earlier pioneer settling it makes fascinating reading.

After pointing out the great difficulties which surround any effort to obtain quantitative information imposed by the absence in those times of any adequate knowledge of malaria, its confusion with typhoid fever, and so on, the author takes up in detail the material he has collected regarding each one in turn of the five States comprising the area dealt with—viz. Illinois, Missouri, Iowa, Wisconsin, and Minnesota, these States having been chosen as best likely to yield the information desired. In each State there was a long interval (epidemiological latency, the author terms it) before malaria became prevalent—a strong argument for the view that malaria was not indigenous in the Western Hemisphere in pre-Columbian times. This period of healthiness was succeeded by such prevalence of the disease that, as the author says, malaria in the nineteenth century was the American disease. The pictures gathered from many sources give a grim insight into what the condition along the rivers and in other early settlements must have been. With more settled conditions and a more stabilized population there followed everywhere, towards the end of the century, a great decline in the incidence, amounting in a large part of the area to virtual disappearance of malaria (and with it, we may interpolate, the curious high prevalence of blackwater fever in America).

It is not possible in a short notice to do justice to the wealth of detail and great interest attaching to what the author has written in regard to the causes which led to the decline of malaria; suffice it to say that he has closely and objectively investigated each possible factor, including a most instructive review of the part played by quinine—again not quite what might have been supposed and a most illuminating sidelight on the early history of this drug. The work concludes with a very full bibliography of the many sources of information consulted.

REGIONAL ANATOMY ILLUSTRATED

Illustrations of Regional Anatomy. By E. B. Jamieson, M.D. Complete volume. Seven sections. Sixth edition. (320 illustrations. 75s., plus 10d. postage.) Edinburgh: E. and S. Livingstone. 1946.

This work has now been published in a single complete volume, the sixth edition. It comprises seven formerly separate sections: I, Central nervous system; II, Head and neck; III, Abdomen; IV, Pelvis; V, Thorax; VI, Upper limb; VII, Lower limb. These sections can still be bought separately in their original form, each section being fitted into a loose-leaf cover in such a way that any plate can be removed for independent use and afterwards replaced, when desired, in the holder. The total number of plates, many of which have been distinctively coloured, is 320.

In Dr. Jamieson's preface to the sixth edition he gives an account of the origin of the first five sections of the series—

namely in response to a demand by his students for a permanent record of the blackboard drawings which he made to illustrate his lectures. This demand was met by Dr. Jamieson and his artist at that period, Mr. E. Pierce, who together produced a "First Series—Sections I to V—partly on the foundation of the original blackboard drawings, partly by drawings from actual dissections, while others were built up by a process of reconstruction of muscles, vessels, nerves, and other soft parts, on a framework provided by a drawing of the bones of the particular region to be depicted. Later, with the help of the artists Mr. R. W. Matthews and Mr. J. M. Philp, the series was completed by the production in 1936 of Sections VI and VII. The illustrations have the merit of clarity, which is largely due to distinctive colouring and simplicity, the latter being rendered possible by the method adopted of combining previous knowledge of topographical relations of the soft parts, with a foundation consisting of a skeletal framework of the region. The clearness of the drawings has been greatly enhanced by the skilful manner in which the names of the parts are given in full, or as easily recognized abbreviations, and their position indicated by pointer-legends—either black pointers on a neutral white background or white pointers on a black background, as in Plate 169 A and B. Improvements on former editions have been effected in several important respects—namely: (1) replacement of some of the older drawings by new; (2) addition of new drawings; and (3) the enlargement of parts of certain figures, which have been printed as separate plates at a greater magnification—e.g., Plate 98: "Contents of the Middle Ear."

The production of the sixth edition, of *Illustrations of Regional Anatomy* in book form as a single volume, will no doubt satisfactorily supply the demand for such a book as an alternative to the older type of edition, in which the plates comprising each separate section are bound together in loose-leaf covers, and the single volume will be found more suitable for use by graduates and students who have passed the pre-clinical stages of their curriculum.

CLINICAL CARDIOLOGY

Heart Disease. By Samuel A. Levine, MD, F.A.C.P. Third edition, revised and reset. (Pp 462, illustrated 30s.) London: W B Saunders Company 1945

The general plan of this work remains unchanged, but a number of additions have been made to bring it up to date. A series of topics has been chosen which cover pretty well the most important points connected with disease of the heart. Each chapter is a self-contained discussion of the matter with which it deals. The treatment is very readable; the author discourses in a pleasant style, drawing much upon his wide experience and quoting interesting cases which illustrate his points. He does not fail to refer to his own mistakes, those experiences are always valuable, for often they are the most instructive.

The book is written chiefly for men in general practice, and accordingly much stress is laid upon the importance of bedside diagnosis without resort to elaborate investigation. Dr. Levine shows fully how very far the unaided senses, when properly trained, can go in the diagnosis of cardiac disease. The book will also be very useful for the senior student and for the general physician; in fact, the cardiologist will read it with interest and profit. The author gives his own views and ideas freely, and many of his reflections are stimulating; all the more so because they differ from those usually made. There is a long section on electrocardiograms—actually nearly a third of the book. This is well set out and most of the illustrations are good. The style is rather too discursive, and it would be easier to assimilate the facts if there was more summarizing. The chapter on heart failure is perhaps the least satisfactory—mitral stenosis is not the best example to take, although it is so common.

SCHEMES FOR MEDICAL CARE IN THE U.S.A.

Prepayment Medical Care Organizations. By Margaret C. Klenz. Bureau Memorandum No. 55. Third edition June, 1945 (Pp 148 25 cents.) Washington: United States Government Printing Office

This report is a significant addition to the evidence of the rapidly growing interest in the United States in schemes for the provision of medical care by insurance of some kind. It gives

particulars of 235 schemes in the U.S.A. and 16 in Canada which were in existence in April, 1945.

The development of these organizations can be traced mainly to voluntary industrial schemes in which both employers and employees took part; but in 1917 the State of Washington passed an Act which required employer and employees to share equally in the cost of medical care for accidents and injuries, and a few other States have followed. Many of the schemes have been fostered by groups of doctors in cities, others resemble those of our trade unions and friendly societies. Medical societies in various parts of the country, particularly on the Pacific side, have sponsored many of them, and it is estimated that about six million people were entitled to a pre-paid service of some kind in 1945. The extent of these services varies greatly, many of them tending to limit the benefits to surgical care in hospitals. Comparatively few give a comprehensive service, and nearly all of them are under the aegis of the medical societies have an income limit. This is not the case in the few which are sponsored by the Government. There were 100,000 doctors in active practice in the U.S.A. in 1941, and of these 44,000 had indicated their willingness to participate in pre-payment schemes.

The report will be found of interest to those who study the growth of the world-wide movement towards making medical service available in a self-respecting way for those of the community who need it but cannot meet sudden and extensive emergencies. There is little in any of the schemes which is not familiar to members of the profession here, except that the subscriptions seem to be on an ampler scale than in this country.

Notes on Books

The Imperial Bureau of Animal Breeding and Genetics (Hendry's Buildings, West Main Road, Edinburgh) has issued as one of its technical communications a monograph by JAMES ANDERSON, F.R.S., M.P.C.V.S., of the Experimental Station, Nanyasha, Kenya, on *The Semen of Animals and its Use for Artificial Insemination* (price 7s 6d). A foreword by Dr J. E. Nichol, deputy director of the Bureau, notes the wider realization in recent years of the possibilities of artificial insemination as a method to aid the development and improvement of livestock production, especially of dairy cattle and to control disease. In 1933 the Bureau published a review of the subject by Dr Arthur Watkinson; in the present monograph Dr James Anderson gives a comprehensive summary of the voluminous literature which had accumulated up to the close of 1943, with some later references in a supplement. There is a full bibliography.

Dr FRANK C. EVE, many of whose writings on the subject have appeared in these columns, has published a small book, *Artificial Respiration Explained* (E. and S. Livingstone Ltd., 7, Teviot Place, Edinburgh 3, plus 3d. postage). In Chapter I Dr Eve explains natural respiration, and in Chapter II artificial respiration (mouth-to-mouth, circulation, ventilation of the lungs); in Chapter III he reviews the situation concerning the three chief methods of resuscitation, and others; in Chapter IV he discusses causes and treatment of asphyxia, and in Chapter V gives brief instructions in the chief methods, including, of course, the rocking method associated with his own name. The text is freely illustrated with line blocks and reproductions of photographs. The language is simple and should be well understood by any intelligent first-aiders.

The Industrial Welfare Society, 14, Horseman Place, Westminster, S.W.1, has issued two new publications. The first, entitled *Doctors' Conference*, reports the proceedings at Leicester College, Nottingham, last August, and includes papers by Lieut.-Col. G. R. Hargreaves on "Integration of the Serviceman and Citizen," and Lieut.-Col. T. F. Main on "Some Aspects of Personal Maladjustment." This report of 120 pages costs 5s 6d. The second pamphlet, entitled *Points for Planners* (price 1s 6d) is a guide to firms planning accommodation for welfare and personnel departments in new or adapted premises. There is a section on first aid and health services.

The report of the Director-General to the Council of the United Nations Relief and Rehabilitation Administration for the period April 1, 1945, to June 30, 1945, is published in London for U.N.R.R.A. by Barrup Matheson and Co. Ltd. This, the third of the series, describes a period of rapid expansion in which U.N.R.R.A. entered upon its first large-scale activities. The main subjects dealt with are supply operations for relief of distress; care and repatriation of displaced persons; health, welfare, and other services; liaison and negotiations; finance; allocation and provision of supplies, including medical and sanitary equipment; and organization and personnel.

examinations in food inspection and inspection of premises, students are to keep a day-book of their practical work throughout the course and examiners are to take account of it in assessing marks.

In some ways the new courses will be more exacting than the old for students, and also for teachers, because instruction will be more demonstrational and not merely supervisory, as so much laboratory instruction tends to be. There are, however, exemptions from classes for students with appropriate clinical or public health experience, and the combination of academic study with approved part-time practical occupation, which the scheme makes possible, should provide a good training for medical officers of health. It should be clearly understood that the new system is intended to provide an adequate basic training in public health, by means of the preliminary course and certificate, for all officers wishing to work in a public health department. The limited numbers who aim at being medical officers of health will go on to the diploma; the others, presumably, will seek a higher qualification in the particular specialty in which they are engaged, whether it be child health, tuberculosis, infectious diseases, venereal diseases, or some other recognized field of public health work. It is to be hoped that employing bodies will fall into line and cease to require all entrants to the service to hold a diploma or degree in public health.

FLUORESCENT TRACERS

In this age of atomic energy much work has already been done on the use of radio-active isotopes for tracing the metabolism of compounds in the animal body. And now, following the identification of tubercle bacilli by fluorescence microscopy, it is interesting to read that the property of fluorescence is being used to trace the location of particles in tissue.

Yagoda and Donahue¹ have shown that many minerals the dust of which is toxic are also represented by natural specimens having the property of fluorescence under ultra-violet rays. The fluorescent mineral is identical with the more abundant non-fluorescent ones in gross chemical composition, hardness, density, and solubility; it differs only in containing a trace constituent held in solid solution which serves as an activator for the transformation of ultra-violet rays to visible light. The fluorescence of these substances, inhaled as a finely divided dust, persisted after being acted on by tissue fluids and reagent solutions used in the preparation and staining of thin sections. The sections of the lung on a slide could also be incinerated at 400° C. in a muffle furnace without destroying the fluorescence of the mineral dust; the fine dust particles were in fact best observed in the resulting ash pattern. Yagoda and Donahue describe experiments with three fluorescent materials: willemite, a zinc silicate with an intense green fluorescence; hyalite, a hydrated variety of amorphous-free silica with a pale-green fluorescence; and scheelite, a calcium tungstate with a fluorescence which varies from blue to yellow according to the molybdenum content. The lungs of a rabbit were insufflated with powdered willemite which passed a 100-mesh screen, and, after 18 hours, examination of the lungs and trachea under ultra-violet light showed the dust adhering as a continuous film on the mucous lining of the trachea and as scattered collections on the cut lung surface, and microscopical investi-

gation disclosed that the particles were located within the bronchi and alveoli. In the second experiment hyalite was injected subcutaneously into a rabbit, which was killed 30 days later. Sections of the nodules at the points of injection, when examined under ultra-violet rays, revealed the presence and distribution of the foreign dust particles by their characteristic pale-green fluorescence. Lastly, animals were exposed for several months to scheelite, and here fluorescence microscopy showed the particles to be located in dense deposits within the interalveolar septa, usually in the vicinity of small- to medium-sized bronchi. Finely granular, evenly distributed particles were also seen in the septa, and in lesser amounts uniformly distributed throughout the lung. Some was found in the periphery of the peribronchial lymph nodes.

This work suggests that fluorescent-tracer technique may become a valuable method of histochemical investigation of inhaled dust, particularly in laboratory investigations designed to simulate conditions in mining or industry. The fluorescent mineral may be used as the dust for investigation, or it might be added in small quantities to the non-luminous variety; or where a fluorescing specimen of identical chemical composition is not available the tracer technique might be used by adding a fluorescent inorganic preparation having density, solubility, and particle size distribution similar to those of the dust under investigation; it might be assumed that wherever a fluorescent particle was observed it was accompanied by the dust.

STUDENT HEALTH SERVICES

The Social and Preventive Medicine Committee set up by the Royal College of Physicians of London in 1942 has now presented a third interim report, giving further and closer attention to its earlier recommendation "that student health services should be available in every medical school, and that under the general supervision of the head of the department of social and preventive medicine they should be used as an instrument of teaching." No final decisions could be reached as to the medical staffing of such services, especially in regard to the provision of treatment, until more was known about a National Health Service. It was also premature, for the same reason, to set out any details of a "student health centre" of the type suggested in the committee's original report. Nevertheless the evidence, mainly from students themselves, revealed such a disquieting position that it seemed urgently necessary to bring the matter to the notice of university authorities. Moreover, though the committee originally confined itself to the narrower question of the health of medical students, it became clear that all university students must be considered. The present report therefore takes up the broad issue of health services for the undergraduate (and the resident graduate too) and gives guidance on general lines of policy without going into detailed suggestions. The evidence before the committee has convinced it that there is a serious amount of sickness among university students; that many university authorities are almost wholly indifferent to any measure of preventive medicine; that facilities for care of sick students (except those suffering from serious illness) are sadly deficient; and that matters of diet and lodgings are in some instances given only perfunctory attention from the point of view of health. The recommendations, briefly summarized, are as follows: (1) Universities should accept greater responsibility for the health of students. (2) Arrangements should be made for medical examination after entry and periodical examinations during the student's stay, to detect physical and mental disabilities and to indicate available means for

¹ *J. industr. Hyg.*, 1945, 27, 193.

forming a complex compound with iron. Other substances, such as formaldehyde and lactic acid, may help in the production of acidosis. It is interesting to note that Rees suggests that the oxidation of methyl alcohol is checked by the consumption of ethyl alcohol, and states that a sign of poisoning may be averted if it is drunk once or repeatedly after the consumption of methyl alcohol.

RHEUMATIC BRAIN DISEASE

It is common knowledge that rheumatic fever involves the central nervous system. Sydenham's chorea being the best-known example. Recent researches conducted in the United States suggests, however, that the incidence of lesions in the brains of patients with a history of rheumatic fever is far greater than has been realized before. In a review of his work Bruesch¹ has pointed out that in only one of thirty patients who had rheumatic valvulitis was the brain free from changes. These changes consisted of obliterating endarteritis of the small meningeal and cortical vessels with subsequent gross or microscopic softening in the cerebral cortex. They are clearly a sequelae from cerebral embolism occurring in patients with mitral stenosis during auricular fibrillation. Involvement of the brain may arise many years after the acute stage of rheumatic fever. The possibility that these lesions may give rise to mental symptoms led Bruesch to study a group of 500 consecutive necropsies in a mental hospital. He found evidence of rheumatic heart disease in 5.3% as compared with an estimated figure of less than 1% for the general population. Among schizophrenics the incidence was as high as 9%. Bruesch discusses a possible causal relation between rheumatic fever and various types of mental disease, but it is clearly desirable that any such conclusion should be deferred until more statistical evidence is available. Even if further work should confirm the results obtained by Bruesch, the relation between schizophrenia and rheumatic disease might well prove to be a concurrent nature not unlike that of tuberculosis. It is also said to be relatively frequent in schizophrenics.

It has been stressed by Bruetsch and others that the vascular changes in the brain are not pathognomonic of rheumatism, but may also be found in other conditions—for example, bacterial endocarditis. It remains to be seen whether recent work on allergy may throw light upon the pathogenesis of the lesions, which are not unlike those described in anaphylactic experiments after protracted sensitization.² This would place the rheumatic lesions in line with periarthritis nodosa, for there is now strong experimental³ and pathological^{4,5} evidence that this condition is an allergic reaction, and, perhaps, also with thromboangiitis obliterans. Both conditions are now assuming some neuropathological importance, as they appear to affect the brain more often than was previously known.⁶

The main library of the Royal College of Surgeons was not seriously damaged when other parts of the building were bombed, and the books have now been returned to the shelves. Several tons of books had been evacuated to Downton Castle, Ludlow; Alfinch Court, Worcester; and the National Library of Wales. Rearrangement of the Library is now proceeding and the Reading Room is open once more to students from all parts of the world.

NOTES ON THE PSYCHOLOGY OF PRISONERS OF WAR

BY

A. L. COCHRANE, M.B., B.Ch.

Capt., R.A.M.C.

Prisoners of war have of late enjoyed and suffered much of the limelight, psychological and otherwise, but in general it is the late, rather degenerate, form of the species—"the ex-Kriegie" or "liberated P.O.W."—who has kept the centre of the stage, and there are, I think, still some points about the psychopathology of imprisonment which merit discussion.

A word about terminology: I have throughout used the word "Gefangenitis"—chiefly because I like it; but it must not be read to imply any pathological condition. It is of course impossible to say what the normal reaction to P.O.W. life should be; even if adaptation is taken as a criterion there is a further difficulty. Those who were best adapted to imprisonment found the greatest difficulty in readapting in England. The Freudian criterion of ability "to work and to love" is also of little help in differentiating "normal" prisoners in a solely male population where most work helped the enemy. It is used here simply to describe the psychology of Gefangenitis.

Acute Gefangenitis

One of the most interesting facts about the psychology of imprisonment antedates the surrender, and it is odd indeed that it should have attracted so little attention. I spoke about this to a very large number of prisoners, and the extraordinary fact emerges that practically none of them even considered the possibility of their being taken prisoner. My own case is fairly typical. I knew for five days that we were fighting a rearguard action on Crete; I had a good idea of what had happened at Dunkirk and in Greece; I visualized death and wounds fairly often during that period, but I never thought of being taken prisoner, although the impartial observer, had he been about, would probably have put our chances of being taken prisoner at about 2 to 1 on, even on the first day. It would seem, therefore, that there was some strong unconscious factor inhibiting normal reasoning. The "censor" apparently "passed" thoughts of death, while "blue pencilling" thoughts of imprisonment—a fact suggesting that rather deep unconscious factors are involved—and it appears reasonable to look for some general psychological reaction among those who were taken prisoner.

It is unfortunately difficult to write with certainty about those early days. There were no mass-observers about, and each prisoner had other interests more pressing than a minute dissection of his fellow prisoners; still, the general impression was so striking that a generalization can be risked. The simplest way is to describe the extreme case, not the average. He will be lying down, alone, and will be silent. If others are near he may exchange a few words, but will, oddly enough, not grumble. If one asks how he feels he will almost certainly tell you to "f—k off," but if pressed will say he's "b—d" or "dead." In appearance he will be dishevelled and dirty and unshaven, even though water be plentiful and he has a razor in his pocket. Orders and requests by his own officers will have no effect on him; he will obey his captors slowly and sullenly. He will be deaf to all ideas of escaping, will often be surprisingly uninterested in food. Such were the extreme cases, which were not rare; but nearly all showed something of the syndrome.

Those prisoners whom I saw on the north coast of Crete after the surrender had been well-disciplined soldiers a few days before, interested in their appearance, and full of initiative. Since then they had made severe physical exertions; they had been hungry and probably thirsty; they had been heavily bombed and seen their fill of sudden death; they had been separated from their officers, and they honestly believed that the Higher Command were dithering incompetent idiots.

With such a mass of possible factors it is at first difficult to say whether the actual experience of being taken prisoner had any effect. One is tempted to say that they had been through so much that the final result is not surprising; but a short examination shows that there are certain difficulties inherent in the obvious explanation.

Hunger and thirst do not usually lead to inactivity—quite the reverse; the belief that the Higher Command were dithering idiots, although common in the Middle East at that time, did not usually have such catastrophic effects. Many, too, had been separated from their officers during the retreat and had retained their discipline and initiative, but when hospitals were reconstituted after capture there was no return to law and order. It is true that they had lost the stimulus of fighting, but they still had the duty of escaping. Yet it is remarkable how few escapes took place in the early days of captivity, although the opportunities then were plentiful. The bombing was severe in Crete; but it was a thing of the past, and can hardly have been responsible. Fatigue is admittedly a possibility; but the worst fatigue was over, and they were capable of further great exertions under German orders. It therefore seems possible that part of the syndrome, at any rate, was due simply to being taken prisoner.

Subjectively my own memory of the period is chiefly one of colossal inertia, which was thrown into relief by the fact that I had a lot to do. I was working at a small hospital, and as I was the only German-speaking M.O. had a fair amount to do in addition to the ordinary medical work. I remember waking each morning and being unable to get up. I was not tired—I was just apathetic; it was often an hour before the remnants of my Presbyterian conscience drove me down to start work. And during the whole of that period every act, every decision, required an effort out of all proportion to the circumstances.

I was very forcibly reminded of another prisoner I had seen during another war. He was a Moorish cavalryman who had been slightly wounded and brought to our hospital. He died—although his wound was of no importance and there seemed no other medical cause for death. There appeared to be a very definite connexion between the Moorish *jelo de se* and the symbolic death of our acute gefangenitis.

Subacute Gefangenitis (Dulagitis)

The new prisoner reaches his first transit camp a few days or a few weeks after capture. He looks forward to it as a centre of some sort of organization; it brings hopes of letter-writing and regular meals, baths, and modern sanitation. He is nearly always bitterly disillusioned. He was, at any rate, in 1941 at Salonika, which was the first transit camp for all prisoners captured in Greece and Crete. I was there from June to Nov., 1941, and it is on my experiences there that this part of the article is based. I have, however, discussed the matter with other M.O.s who were in the Libyan and Italian camps, and the pattern appears fairly constant.

Here again there is an excess of factors, all possibly effective, so that it is difficult to distinguish cause and effect. There was first of all hunger: on a diet of 1,000 calories everyone is nearly always hungry. There was also almost always a marked shortage of water. Nearly everyone had diarrhoea, and most of them hypoproteinaemic oedema; the sanitation was deficient and primitive to a degree; overcrowding was appalling; and there were innumerable bed-bugs. The nervous tension of the camp was kept at breaking-point by shooting inside the wire every night and often during the day. The news in the second half of 1941 was not very good, and morale was very low. The average P.O.W. arrived at the transit camp still in the apathetic stage, and the psychopathology of transit camps really consisted of the fate of apathy. There was inevitably one group of prisoners who remained apathetic; they became more and more horizontal, ceased washing, and ceased caring. They were difficult to treat; a few died of intercurrent infections.

The other symptoms are best considered under various headings.

(i) "Midsummer Madness."—People normally sensible and eminently reasonable did or said things which showed they had completely lost their sense of proportion. I give two examples from officers who might be expected to have retained their equilibrium better than others: (a) There were relatively few M.O.s at one period, and as we were receiving only 1,000 calories we wished to share out the work. One doctor refused to work, saying he wouldn't work unless the Germans gave him more food—regardless of the fact that it meant others had to do more work in his absence. (b) A padre asked me to translate a letter into German in which he

expressed his undying devotion to the Führer! When I expressed anger and astonishment he seemed very surprised. Associated with this was a certain amount of collaboration with Germans, among both Serbs and British. One case was particularly disastrous to the British in the camp. These people were "strangers and afraid in a world they never made." They had woken up in a new world where the old standards no longer existed and where they searched in vain for new.

(ii) Appearance of neurotic symptoms as seen on the sick-parades. There were numerous hysterics and hosts of hypochondriacs.

(iii) *Furious Aggressive Tendencies*.—These were directed against the Germans and, oddly enough, against their own officers (including M.O.s!). In conversation no officer who left Crete, free, escaped the most biting criticism, and death did not save many others from the most vicious attacks. It was also typical that the attacks were launched in the foulest possible language. The extent of the feeling can be judged from the fact that it was generally assumed, without any evidence to support it, that one very senior officer had committed suicide. It also appeared between the various national groups present in Salonika—i.e., Australia, New Zealand, Ireland, England, Scotland, India, Cyprus, Palestine, Yugoslavia. There were some bitter fights between the various national groups. This feeling was very carefully fostered by the Germans.

(iv) *Fatigue*.—This was widespread, affecting all ranks and all nationalities. People normally slept on all their worldly possessions, and took them with them on parade. Distrust was complete. I remember being unable to sleep at night because I had left some reserve food with such respectable people as the Friends Ambulance Unit. I am happy to say that it was still there in the morning.

The picture is admittedly complex, but I think a certain simplification can be introduced by discussing the acute "hunger" syndrome separately. I saw its effects at various other times, and it is reasonably well known. (We were on 1,000 calories diet, so the use of the word "hunger" is really justified.) The first signs are increased motor activity directed towards getting food, accompanied subjectively by irritability and the hunger pangs. Then follows a fairly rapid deterioration of the conscience, characterized in Salonika by first stealing from the Germans, then from other P.O.W.s, and then from one's friends. Next, activity gets gradually less, and finally apathy appears if the diet is low enough. This apathy does not appear until there are obvious signs of malnutrition.

If we then, as it were, subtract this syndrome from the whole symptomatology of "dulagiti," there remain the "midsummer madness," the neurotic symptoms, and the ill-directed aggression, appearing as apathy disappeared. The continuing state of apathy could be seen as a continuation of two separate tendencies. It is therefore reasonable to suggest that the psychological mechanisms involved in the early stages of imprisonment probably consist of normal aggression being directed inwards, producing the picture of apathy or symbolic death, and that in the recovering process there is a period of "feeling lost" associated with ill-directed aggression and escapist hysteria.

The reason for this profound effect of imprisonment is harder to guess, but the fact that death was considered by the "censor" preferable to imprisonment suggests that rather deep layers of the unconscious were involved. It is possible that this surrender of male to male involves some unresolved residue of the Oedipus complex.

Chronic Gefangenitis

(a) Psychological Medicine

In general, psychological medicine in imprisonment was very similar to that in peacetime. There were the same anxiety neurotics, hypochondriacs, compulsive neurotics, hysterics, and psychotics as in normal life. Whether they were more numerous than usual no one knows; no statistics or comparable group is available. One inevitable difference was the extent of malingering. It was very difficult for an Army doctor to change from the habitual severity with malingerers to an attitude of complacency if not actual encouragement. In many cases the differential diagnosis between psychoneurosis and malingering was very difficult. Most prisoners felt it their duty to malinger as much as possible to decrease the German war effort, and this idea strongly reinforced any hypochondriac tendency.

Another point of interest was the national preference for particular organs among the hypochondriacs. The French

pain round both rib-margins; the Russians had pains in their backs; the British concentrated on their stomachs, with the "effort" syndrome a good second. The Germans, I gather, had roughly the same interests as the British, but their doctors tended to treat the effort syndrome with cardiazol (leptazol) and strophanthus.

One learned in time how to cure them. The French could always be cured by injections—they preferred injections of liver, but that was too much for my conscience! The Serbs always reacted to massage, the Russians to heat. A barium meal was found to be best for the British stomachs (it was effective before any results were known), and psychotherapy for the effort syndrome. It is probable that the doctor's mistakes of one epoch produce the type of hypochondriac of the next! In 1943 and 1944 it was interesting and frightening to watch the growth of the Tb. neurosis, as the routine x-ray examinations were carried through without any adequate explanation.

Had I done more psychotherapy it would have been interesting to generalize about the aspects of P.O.W. life which had produced the strain causing the appearance of the neurosis. Actually the majority of the neuroses I saw were deep-rooted in civilian life; of the others I can only say that "repressed aggression" seemed the best way to describe what had caused the trouble. Let me give an illustrative case.

A Scot of about 30 was admitted with various complaints, diagnosed as effort syndrome. Psychological treatment was difficult as he refused to talk, but after a few days he came into the open on the subject of why he was not sleeping. He started telling me his dreams, and I was suddenly involved in a very vivid description in broad Scots of a long and very bloody massacre of Germans. His previous psychological history was all right, but he had developed a passionate hatred of the Germans in France in 1943 and during the surrender at Saint-Valery, which was not decreased by the march into Germany. At the beginning he tried violence with Germans—but found, like so many others, that it did not pay. He had then tried to work it off on his companions, but they got quickly tired of it; after two weeks of it myself, I did not blame them. He had then developed his heart symptoms and his sleeplessness. I did not attempt to analyse the case any further, but let him work off his feelings and tried to direct his energies towards escaping and saw him with some success. Other similar cases could be cited, but they would have no statistical importance.

(b) Sex

The secret sexual lives of prisoners were much less lurid than one might have thought, but they were not without interest. There were first of all the secret normal lives in defiance of the medieval German racial laws. They were far more numerous than one would have imagined. There was a certain tobacco factory in the IX area whose history would make a good "Tommy by Warlight" and would doubtless have a great success, and the barbed wire became the linear descendant of the locksmith in its relation to love. Less romantically there was a very definite increase in masturbation. This in general did little harm; but there were a few who became depressed and worried, feeling grossly guilty and fearing all the classical fates of madness, feebleness, and impotence.

As regards homosexuality, the most obvious sign of it was the popularity of dances among the P.O.W.s, which were widespread. The extent of actual sodomy was very hard to judge, not only because it was concealed from M.O.s but also because of its sporadic appearance: there would be a great deal in one working party, where it spread rapidly by a sort of infection, while neighbouring working parties would have none; but the general incidence was probably very low. The cases of which I heard fell into the following groups. (a) Those initiated by a P.O.W. who had been an active homosexual before the war. One of these stated—for what it is worth—that "P.O.W.s were much more easily seduced than civilians." It happened that I treated two who had been seduced in this way, for non-psychological complaints, but they spoke to me about it and claimed to have had heterosexual imagery throughout. It appears to have done them no harm, apart from some increase in guilt feelings. (b) Those initiated by regular soldiers, who had not previously been homosexual. There seems to be a vague homosexual tradition among regulars, and they turned to it when bored. In general, homosexuals were treated more

I have the impression that sexual abstinence did not prove such a psychological strain as might have been expected.

(c) Hunger and Economic Factors

British prisoners were not chronically hungry in general. The Red Cross parcels prevented that; their diet was monotonous, but they were rarely hungry. On the other hand, there were numerous groups of P.O.W.s who were much less well off than the British—e.g., French, Serbian, and Russian. In "mixed" hospitals these groups met, and one was able to judge the effect on behaviour of small groups, living on different economic levels, under otherwise identical conditions. The calorific levels were approximately 2,900 (British), 2,100 (French), 1,700 (Serbian). A "class" system established itself at once, the British "hiring" for food or cigarettes French or Serbs to do their washing and other dirty work; the French employed the Serbs. Ill-will followed rapidly on both sides, but it was striking how much more vocal and aggressive the higher-calorific groups were in criticizing the lower as regards the quality of their work and their demands for payment.

I was able to carry out a questionnaire on a group of Serbs as they left the hospital. A Serb cadet officer acted as intermediary, and no one suspected that it was being done. The questions asked were: Do you think more or less of the British after meeting them in this hospital, and why? The result was that 87% thought less, and the reasons given were: "their bloody condescension" and "their damned parcels." The first on analysis proved to refer to the way in which the British gave them occasional food and cigarettes—an interesting example of the failure of charity to solve economic problems. It is certainly true that the parcels saved our health, but it is equally true that they ruined our reputations.

It is obvious that these feelings were partly nationalistic, but it was made very clear, at another hospital, how important the economic factor was. This was a hospital solely for tuberculosis, and permission was obtained to give all patients British parcels. This hospital was even more international than the other, but the international rows were very much fewer. I also had an opportunity of experiencing this problem myself. It happened that the staff of one hospital consisted of two French M.O.s and one British (myself), and ten British orderlies. As the French M.O.s got very few parcels, my standard of living fell considerably below that of my orderlies. I remember being amused and ashamed at my irritation with what I felt was my orderlies' condescension, and by the general increased friction between the orderlies and myself during this period.

It must be stressed that in all these cases the "lower" class has been on a very low economic level, and are therefore not comparable with the conditions in civilian life. It was unfortunate, too, that no groups presented themselves when the differences were solely qualitative and not calorific, but the whole was impressive evidence for the importance of the economic factor.

General

Apart from all these minor groups of psychological phenomena, it is reasonable to ask if there were any general phenomena appearing among P.O.W.s which might be attributed to the effect of imprisonment itself. I have discussed this with many P.O.W.s, and there seems to be general agreement about the following two: (i) increasingly frequent attacks of bad temper; (ii) increasing lack of enterprise and initiative, leading in some cases to apathy. In general one could say that the first year was spent in adaptation, the second was the best year, the third began to be a strain, and the fourth and following years left no one unscathed.

The simplest and most probable explanation of these is again, I think, the problem of aggression. Mechanically it is easy to visualize the syndrome as being due to the aggression slowly turning inwards, with occasional "break-through" to the outer world. Theoretically it is not, I think, surprising that aggression should loom so important in Gefangenitis. Sex and food deprivation produced no major conflict in themselves; they merely caused aggressive hate directed towards the Germans, and this increased aggression, perpetually tantalized by the barbed wire and the ever-present guard, could find few outlets compatible with survival as a prisoner. Hence the conflict and the neurosis.

The Returned P.O.W.

On this basis one would naturally expect the returned P.O.W. to have difficulty in coping with this suppressed aggression, and that in general he would be "in revolt"; but on this subject there are many more objective observers than myself, and I feel it is better left to them, with, however, the plea that some attention should be paid to the psyche of repatriated prisoners. At my own medical board there was not one question which could in any way be construed as showing interest in my feelings, and they did not even measure my B.P.!

Another point worth making is about their guilt feelings. These are very strong among repatriated P.O.W.s. It is not perhaps generally recognized that this is a new phenomenon caused by liberation. Little was seen of it among P.O.W.s while still in captivity. It is part of the liberation syndrome, which has been freely confused with "Gefangenitis."

DENTISTRY IN NATIONAL HEALTH SERVICE

TEVIOT COMMITTEE'S FINAL REPORT

The Interdepartmental Committee on Dentistry under the chairmanship of Lord Teviot, which was set up nearly three years ago, has completed its work. It issued an interim report in November, 1944,¹ in which it recommended a comprehensive dental service as an integral part of the Government's national health scheme. It will be recalled that the White Paper declared that a dental service must be an exception to "comprehensiveness" because there were not, and would not be for some years, enough dentists to provide it. The final report of the committee is now published.² In many respects it accords with the report of the Goodenough Committee, and applies to dental education some of the recommendations to which the Goodenough Committee gave a wider reference.

Recruitment of Dentists.

The number of dentists practising in Great Britain is just under 14,500. The committee states that up to a total of about 20,000 there is no likelihood of securing entrants more quickly than they are needed. To achieve a total of 20,000 in 20 years will call for an intake into the profession of just over 800 a year. The student entry will have to be larger than this because of the proportion of students—about 10%—who fail to qualify. In pre-war years the annual student entry was only 340, and during the war it fell below 300.

Although so similar to medicine in training and practice, dentistry may, owing to its more restricted field, lack the appeal which medicine makes to the young person in search of a career. The work may seem distasteful to many. It imposes the strain of continuous application to precise operations and confinement to the chair-side. The range of financial reward is not as high as in medicine, particularly for salaried posts, yet dental education is costly for the student, and after qualification he may require considerable capital to set up in practice.

The committee suggests certain measures for bringing dentistry to the attention of public and secondary schools. The dental schools also should make themselves well known to potential students. It may be expected that the increasing appreciation of dental health and the rising demand for treatment following the inclusion of dentistry in the National Health Service will have its reflection in the added status and attractiveness of the profession.

Dental Education

It is considered by the committee that all dental schools should be integral parts of a university; at present two schools (Edinburgh and Glasgow) are not. The Government, the universities, and the dental teaching hospitals should make available to dental students better educational facilities than exist at present. The first problem is to find teaching staff of requisite quality. Teachers should be encouraged to engage in dental research and to study all developments of their subject, and should have sabbatical leave. All teaching appointments should be adequately remunerated with graded

¹ *British Medical Journal*, 1944, 2, 765.

² Cmd. 6727. H.M. Stationery Office, Kingsway, W.C.2. Price 1s.; post free 1s. 1d.

salary scales, reasonable increments, and superannuation rights. The Goodenough Committee recommended a national range of salaries for medical teachers, and the same should obtain for dental teachers.

At present four universities although they have medical schools, do not provide facilities for the teaching of dental school students. It is considered unlikely that Oxford will be able to contribute to dental education in the near future. Cambridge is understood to be prepared to assist. The establishment of a dental school at Aberdeen might eventually be explored by the university. In Wales favourable consideration is likely to be given to the establishment in Cardiff of a complete course of training for a degree in dentistry. It is hoped that all the schools will in future admit women students.

More could be done in offering financial assistance to prospective students. As a short-term policy a certain number of State scholarships designated to dentistry should be offered for open competition. Loans as distinct from scholarships or bursaries are not regarded as desirable. Awards should not be conditional upon the student's undertaking public dental service after qualification. The need for better postgraduate education is stressed, and a postgraduate teaching school in London is recommended. To meet the cost of improving and extending dental schools and adequately remunerating the teaching staff the committee recommends a Government grant of £1,250,000 for capital expenditure, with annual grants of £100,000, rising to £300,000 within five or six years.

Government of the Dental Profession

The committee (except for one dissenting member) urges that dentistry should now be self-governed instead of being within the orbit of the General Medical Council. The separate Dental Council which would replace the Dental Board would include one representative from each of the 16 universities or corporations granting degrees or licences in dentistry, eight direct representatives of dental practitioners, three Crown nominees and, for the purpose of education and examination functions six members appointed by the General Medical Council. The committee makes one comment here.

An independent position need not be an isolated position. Had we thought that these proposals would lead to the isolation of dentistry from medicine in general we should have rejected them. Our view is, however, that the professional association of doctors and dentists can be all the closer and more cordial when each profession is self-governing.

The dissenting member, Major-Gen. J. P. Helliwell, holds that it would be a profound disservice to dental education if the Dental Board were reconstituted as an independent council, and he adds that although the General Medical Council agreed to the proposal "it did not seem to show any great enthusiasm for the transfer of its functions with regard to dental education," and only agreed to it on condition that the reconstituted council should include additional members from its own body. He quotes the President of the General Medical Council as stating in his evidence before the committee that he was of opinion that dentists should possess a basic medical qualification.

Certain amendments of the law are suggested by the committee in the light of its proposal that a comprehensive public dental service be instituted. One suggestion is that means be taken to bring to an end the shops to which the public are invited by advertisement to bring dentures for repairs without the intervention of a dentist.

Dental Research

The encouragement of dental research is regarded by the committee as a duty of the whole community. The necessary funds should be voted by Parliament, and the reconstituted Dental Council should be divested of the obligation, under which the Dental Board laboured, to devote surplus funds for certain purposes, including research. Existing agencies for dental research should be utilized, and not only should there be a dental member on the Medical Research Council but that body should be advised by a Dental Research Committee.

"The need, stated in its simplest terms, is that much more dental research of high quality should be done. We need to acquire further knowledge of the oral tissues in health and disease and of their relation to general fitness; to find and assess methods of applying that knowledge in order that dental disease may be prevented; to

determine the best means of treating dental disease, and to establish standards for the drugs and materials with a dental surgeon employs. Dental disease (including disease of the oral tissues) is one of the most common of all diseases. The committee have proposed that the community should undertake a responsibility for the dental treatment of all who need it. It therefore becomes a public duty, as well as being manifestly in the public interest, to find out more about dental disease and how it may be prevented."

It is added that oral care is a subject of outstanding importance in dental research, although there are also many other subjects which perhaps do not catch the public understanding so easily and which have an immediate bearing on oral health.

Finally the report deals with the question of dental workers. After setting out the arguments for and against the registration of the dentists' work to operative dentists, the committee unanimously recommends that the institution of an "examination" of that kind should be a proof of a shortage of dentists to work the comprehensive dental service. A scheme for the training of "dental hygienists," whose work should be limited to the scaling, cleaning, and polishing of teeth and the instruction of patients in the technique of oral hygiene, always of course under the responsible direction of dentists, should, the committee recommends, be initiated immediately on such a scale as to provide an adequate test of their value.

The committee held 24 two-day meetings and received oral evidence from 35 organizations and individuals.

HUNTERIAN DINNER AT THE COLLEGE OF SURGEONS

John Hunter was born on Feb. 14, 1728, and died on Oct. 16, 1793. The Hunterian dinner in commemoration of his birthday was held, under an endowment of the year 1813 at the Royal College of Surgeons of England, Lincoln's Inn Fields, on Feb. 14 for the first time since 1939. The revival of this festival after his 118 years and the partial destruction of the College building, was made noteworthy by the presence of many men of high rank in public and professional life, including 22 of the 31 Trustees of the Hunterian Collection, headed by the Lord Chancellor of England, Lord Jowitt. The number of trustees at the dinner would have been 25 if a company of more than 130 but the Prime Minister, the Chancellor of the Exchequer and the Secretary of State for War had to call off at short notice owing to the need for them to attend an important debate in the House of Commons. The guests were received by the President, Sir Alfred Webb-Johnson, Bt., and the Vice-Presidents, Sir Max Page and Sir Hercules Onley, in a part of the ground floor which few could recognize as the scene of havoc depicted in a photograph taken after the air raid in 1941.

When "The Memory of John Hunter" had been honoured in silence the toast of "The College" was proposed (in the absence of Mr. Attlee) by Lord Jowitt, who said that the great traditions of British surgery had won the heart of the country in war and in peace. The Government wanted to bring the best type of recruits to surgery and give them a proper reward, because the active support of the medical profession was essential to any scheme of national health service. Though he could not now say more on the subject he knew that this view was firmly held by his colleague Mr. Aneurin Bevan, who was present at the high table but was not speaking that night.

The President expressed the pleasure of the Council in greeting four Ministers of the Crown, five Ambassadors from foreign Powers, and many representatives of the Dominions which emphasized the imperial and international value and significance of the College and of its proudest possession—the Hunterian Collection and the great Museum which was built round that original nucleus. The medical profession had been rendering service to the utmost of its strength all through the trying times of war, and in this home of surgery, he wanted to pay a special tribute to their colleagues of the nursing profession and to the gallant women who drove the ambulances with care and consideration through the terrors of the blitz. When the time of trial came to the College itself much was spared in the holocaust; though it had been impossible to evacuate scores of thousands of specimens from the Museum many were safely stored, and thanks to Sir Hugh Lett's Herculean labours many

were rescued and the library had been evacuated to safe areas. Much progress was afoot with plans for restoration and for carrying them out. Sympathy and encouragement had poured in from all sources, from the King to the humblest worker in the biological sciences, and from all parts of the world came gifts and promises of future help. Not only had the munificence of Sir William H. Collins already provided an endowment of £200,000 for the scientific departments but the President was able to announce that Sir William had just made a further gift of £100,000 to the College on certain conditions. This then was no ordinary occasion: it marked a milestone in the history of the College. The plans now in hand provided for enlarged museum space, extension of research rooms, rooms for separate study and common-rooms for postgraduates from all parts of the world, extensions of the library, and a great conference hall. The Wellcome Trustees made a magnificent gift, and the Council valued equally with this their collaboration and the help of Sir Henry Dale, so that a group of medical museums could be established in London that would be a Mecca for students from all countries. Thus they carried on the great Hunterian tradition. For the heads of the two Sections of Pathology and Anatomy the Council searched the world for men of the highest attainments and secured the services of Prof. R. A. Willis, of Melbourne, and Prof. F. Wood Jones from Manchester. With their expert help it would set about restoring the greatest possession of British medicine, one of the bases of biological knowledge—a great staff college of learning built up round the collection of the founder of scientific surgery.

The President read a message sent that day to the King expressing deep appreciation of His Majesty's constant interest and encouragement as Visitor of the College, and adding that, thanks to the generous support of scientists in all parts of the world, good progress was being made in the heavy task of restoring the unique museum. The King replied from Buckingham Palace saying:

"Please convey to the members of the Council and Court of Examiners of the Royal College, and to the Trustees of the Hunterian Collection, my sincere thanks for their kind message. As Visitor of the College, I am very glad to hear that the anniversary of John Hunter's birth is once more being observed in the customary manner, and that such generous help towards the restoration of the Hunterian Museum has been forthcoming from your fellow-workers in so many countries."

The health of the guests was proposed by Sir Max Page, and Dr. Wellington Koo, Chinese Ambassador, and Mr. A. V. Alexander, First Lord of the Admiralty, both replied, the former drawing an analogy between a major surgical operation and war and its aftermath; and the latter paying tribute to the great and grand work of Service doctors of every rank. Sir Kenneth Ogilvie proposed the health of the three Hunterian orators since 1939—Prof. A. H. Burgess, Mr. Victor Bonney, and Prof. G. Grey Turner—and contrived in a few words to set forth the character and achievement of the man whom the College delights to honour from generation to generation. Prof. Grey Turner, Hunterian Orator for 1945, replied to the toast.

TECHNICAL ASPECTS OF CREMATION

It has been authoritatively estimated that in the next twenty years the number of cremations in Great Britain will reach a quarter of a million per annum, or about half the total death rate. At present there are in operation 58 crematoria (36 owned by local authorities or joint boards and 22 by private companies), and in 1944 there were 39,016 cremations—an average of 675 at each place. With the gradual change of public opinion on the aesthetics of cremation versus burial it is anticipated that the average will rise to 1,000 a year, and that the number of crematoria will be 250. Some 200 new crematoria are, in fact, planned for erection when building conditions permit. The progress of the movement was more rapid in the immediate pre-war years than at any time in its history, and it will be accelerated during the post-war reconstruction period, when many problems concerning the alternatives of using valuable land for cemeteries and erecting crematoria of appropriate design will call for solution. The fuel technologist as well as the cremation advocate has been responsible for much of the progress. Of the 58 crematoria now operating, 47 employ gas as the incinerating medium, four are coke-fired, five (one of which uses both gas and electricity) are heated by electricity, one uses oil, and one "bottled" gas.

Many cremations are carried out in the hot chamber using preheated air only. There are now eight furnaces at Golders Green. Conversions have been made from coke to gas at Golders Green, Manchester, Sheffield, Hull, Woking, and Liverpool, and further conversions are in prospect. Recent developments have been directed to improvements in technical operation, the application of heat, and the provision of "recuperation" for heating the air required for oxidation. The time required for a complete cremation with gas-heated furnaces varies within narrow limits, about 75 to 90 minutes being typical. Wide differences exist between human bodies, but incineration can usually be carried out in a hot furnace with the aid of preheated air from the recuperator only.

The first really modern incinerating furnaces were installed in this country about 1923. The gas incinerator of to-day is the outcome of long experience, improvements having been made from time to time in the last twenty years. A special burner has been developed which operates with a fan under low pressure for the air supply; this speeds up the cremation and is more efficient. The waste flue gases are conveyed to a tower by rectangular flues, the products of combustion being exhausted into the atmosphere well above the level of the ground. In the natural-draught furnace the burners are arranged in a combustion zone in the ash-pit chamber, which is immediately beneath the grid hearth-bricks or the coffin supports. Where no other manufactured fuel is available the coke-fired cremating furnace is in use.

SUMMER SCHOOL IN SOCIAL BIOLOGY

The British Social Hygiene Council will be holding a residential Summer School in Social Biology, at Wadham College, Oxford, from Aug. 1 to 15. It is being planned to illustrate the scientific approach, through biology, to human life and culture, as well as the ways in which the biological sciences find application in individual and social life. It is designed to appeal to teachers in all types of schools, and others concerned with education. The main course of lectures will deal with broad aspects of social biology of interest to specialists and laymen alike; the evening lectures will be given by distinguished visiting biologists and social workers. A series of practical demonstrations, and of visits to scientific institutions, research departments, and other places of interest in and around Oxford is under arrangement. The fee will be £14 14s. Further particulars may be had from the British Social Hygiene Council, Tavistock House North, London, W.C.1.

Reports of Societies

PENICILLIN TREATMENT OF OSTEOMYELITIS

A combined meeting of the Sections of Orthopaedics and of Surgery of the Royal Society of Medicine was held on Feb. 5 for a discussion on the treatment of acute osteomyelitis with penicillin. Mr. W. B. FOLEY presided.

Mr. VAUGHAN HUDSON described a laboratory and clinical investigation conducted at the Middlesex Hospital. It comprised 37 cases of acute or subacute osteomyelitis in which penicillin had been used. In 30 of the cases the organism was *Staph. aureus* and in 7 *Str. pyogenes*. In the majority, when the case came under treatment, the infection had been present for some days; only 2 were seen as early as the fourth day. The youngest patient (who died) was 1 year old; the oldest (who recovered) was 70. In 6 cases, had penicillin not saved the life of the patient and given time and opportunity for the focus to be discovered, the patient would have died with the cause of his mortality unrecognized. It was proper that the results of penicillin treatment should be regarded with the greatest reserve. The vagaries of this disease were well known, and were exemplified by one of these patients who, after many vicissitudes, recovered from a gunshot osteomyelitis of the femur, after surgical operation, in 1918 and remained well for twenty-five years until he spontaneously developed a recurrence of the disease in the second world war.

The severity of the disease varied very much from year to year and from patient to patient. In one patient there might be a multiplicity of foci, in another the whole of one bone might be affected, and in a third the disease might be localized to one small area. The organism had a peculiar property of hibernation, and if operation was done during the hibernating period the organism was rarely discovered. It was soon apparent that penicillin swept the organisms from the blood stream and reduced the acute lesion to a chronic one, the

Psychology of the One-eyed Man

SIR,—The article on this subject by Lady Duke-Elder and Dr. E. Wittkower (Feb. 2, p. 155) deserves the careful attention of all concerned, both employers and medical examiners. Grievous wrong has been done in the past to men so handicapped, largely through our imperfect understanding of their cases. Let us hope that with better knowledge of their psychology we shall avoid the mistakes of the past.

Having made more than a thousand ophthalmic examinations for pensions after the last war I think there is one point that deserves emphasis. Again and again I found one-eyed men attributing some defect of vision in their remaining eye to the loss of the other eye. They argued that one eye had now to do the work of two, and must, therefore, be severely strained. Any defect of vision in the remaining eye due to astigmatism or other error of refraction was accepted, wrongly, as inevitable and incurable. It should be pointed out to these sufferers that this view is entirely mistaken. A one-eyed man is in one way less liable to eye-strain than before the loss of his eye. All strain arising from errors of muscle balance, such as hyperphoria and/or weak convergence, are eliminated, presumably, by the loss of one eye.—I am, etc.,

Banstead, Surrey.

HERBERT CAIGER.

Ocular Signs in the Prisoner of War from the Far East

SIR,—Since the days of Clive the description of the European released from an Asiatic prison—half-starved, covered with sores, and exhibiting signs of food deficiency—has generally included the words "half-blind." Families with the Indian Army tradition will have heard such stories about their forebears amongst the prisoners of the Black Hole of Calcutta, of Tipu Sahib, and of the days of the great English expansion through India. Baird, Stoddart, and Gale are names that spring to mind, and I would wager that investigation would reveal a high incidence of central scotoma. To come to our times, the literature of the preceding thirty years for ophthalmic signs associated with food deficiency was summarized by R. H. Elliott in 1920 (*Tropical Ophthalmology*). Unfortunately his work had received only passing mention in the standard textbooks of this country until the recent war against Japan. There is nothing new under the sun, and here with these unfortunate partly blinded prisoners of war we have a problem that has engaged the attention of clinical observers over the past fifty years. It used to be said that the great charm of ophthalmology was that it was the one branch of our art that could approach science in its precision. Therefore our care must be to get the ocular signs of this syndrome defined and limited before we become embroiled in controversy over the various subdivisions of dietetic deficiencies in our search for the cause.

In May and August, 1945, Capt. W. M. Rich and I examined a small number of men that had been released at Rangoon. Doubtless some of these men were also examined elsewhere, but at the time of our original article we had not the benefit of the experience of other observers. Our report was sent for censorship in September, and after various vicissitudes was only finally published in the *Journal* of Jan. 5 (p. 20).

Our conclusions were that there were discrepancies between the ocular signs previously described and those exhibited by our cases after their arrival in England. The outstanding points appeared to be that there were no ocular muscle pareses, no peripheral visual field constriction, and that the number of men with signs of a bilateral retrobulbar neuritis (I use the term advisedly) was high, whilst the scotomata to white targets seemed to show a characteristic "tailing" but had some affinity to those of the toxic amblyopias. We also tried to review the relevant literature from the ophthalmic point of view, pointedly skirting ariboflavinosis rather than plunging headlong into a morass of speculation on dietetic deficiencies.

Reports on similar cases can be found in the December copies of the *British Journal of Ophthalmology* and of the *Journal of the Royal Army Medical Corps*. From these reports it would appear that the patient while in Asia exhibits his scotoma, is sometimes deaf (two cases only of the 219 examined have been sufficiently deaf to force the examiner to raise his voice beyond conversational level, and neither of these manifested scotoma), has considerable kerato-

conjunctival abnormality, and that his legs are more often affected than his arms by his food deficiency ("beriberi" is used advisedly). A blunderbuss of multiple vitamin therapy is discharged at him on his voyage home, which achieves considerable improvement, especially with regard to the state of the lesions of his cornea and conjunctiva (as might be expected). In this connexion Capt. Churchill's article is of considerable value in detailing the prison diet.

Since the time of the Rangoon cases some 219 men (all ex-Japanese P.O.W.s) have been referred to this centre for visual defects by their medical officers. In each case a scotometry has been performed, and to date some 54 have been found to suffer from bilateral central scotoma. I hope soon to be able to correlate these findings. Ridley's description of the Thailand cases (*Brit. J. Ophthalmol.*, 1945, 29, 613) showed that, but for the vitamin therapy on the way home, most cases might be expected to show abnormality in limbal vascularization. Even so, a recent annotation in the *Journal* (Dec. 22, 1945, p. 889) has suggested that to the ophthalmologist and his slit-lamp the abnormal limbus is not readily acceptable.

Dr. H. G. Garland (Jan. 26, p. 143) proposed to exclude the B₁ portion of the B complex as a cause for this syndrome, for some reason that he does not state. I regret that I am unable to subscribe to this, as the history of several cases shows that an incipient ocular defect was aborted by the use of thiamin in the prison camps. Rather would I tend to exclude vitamin A, as does Churchill. Vitamin B₁₂ is most definitely involved.

Dr. Garland and Dr. FitzGerald-Moore have suggested that beriberi is a coexisting deficiency picture. Rather than postulate a further subdivision of disease may I be permitted the following comment. Over forty years ago the Japanese noted a definite time relation between the onset of the scotoma and the set of clinical signs which they knew as beriberi or *karkare*. Some 75% of my 200-odd cases of visual defect have claimed that they have suffered from "wet or dry" beriberi, and the interest is that 45 out of my 54 cases of bilateral central scotoma have a history of this disease with a fairly constant time relation between the onset of the two.

The pathological findings in the C.N.S. in beriberi are those of demyelination, haemorrhages, and subacute inflammation of the white nerve fibres and their surrounding membranes. Even allowing for Kagoshima's report, why postulate a simple degeneration without inflammation in the optic nerve, due to a deficiency of only a portion of the B complex? The December *British Journal of Ophthalmology* (p. 655) notes that Major Maynard of the A.I.F. has returned home with some sections of the brain complete from the eye to the occipital cortex. Until his report is published may I be permitted to retain the expression "retrobulbar neuritis," which fits best into the ophthalmic picture.

In conclusion may I express my profound admiration for the ingenuity and skill in improvisation of the medical staff in these camps scattered throughout Asia, who used any available means to hand from shark liver to red palm oil to allay the ravages of this disease. What does amaze me is that there seems to have been no trachoma reported.—I am, etc.,

G. C. DANSEY-BROWNING,
Major, R.A.M.C.

Ophthalmic Centre, Fenham Barracks,
Newcastle-upon-Tyne.

Blindness in the British Commonwealth

SIR,—In a comprehensive survey of this problem (Oct. 27, 1945, p. 557) Prof. Arnold Sorsby states, in reference to the causes of blindness in the African Colonies, "Trachoma is probably rare but not unknown, as was previously believed." So far as Uganda is concerned, trachoma is endemic and is the principal cause of visual disability among Africans. In the sphere of ophthalmic surgery operations for the relief of trachomatous trichiasis-entropion head the list by a long way.

An analysis of 1,000 consecutive case records from the eye department of Mulago Hospital shows: trachoma, 285; diseases of the conjunctiva (excluding trachoma), 164; anomalies of refraction and accommodation, 125; diseases of the cornea and sclera, 79; diseases of the lids, 60; diseases of the uvea, 59; injuries, 48; diseases of the lens, 24; N.A.D. (chiefly tests for fitness as drivers, etc.), 24; diseases of the retina, 23; glaucoma (primary and secondary), 23; diseases of the optic nerve, 21; systemic diseases (including the C.N.S.), 18; helminthic infestation of the eye, 28 (onchocerciasis, 11); ophthalmoplegia, 7; panophthalmitis, 4; phthisis bulbi (bilateral), 3; diseases of the orbit, 3; diseases of the lacrimal sac, 2.

Prof. Sorsby mentions recent studies on onchocerciasis. This condition has been recognized for more than ten years as a serious cause of blindness in certain parts of the Protectorate, notably around the headwaters of the Nile, where the population is exceptionally dense. The 11 cases shown above can give no indication as to its true incidence, for the infected area

is some fifty miles (80 km.) distant from Kampala; these 11 cases had all come from that area. Since we (at present) know no cure for onchocerciasis, its eradication as a cause of blindness is an entomological problem of some magnitude.—I am, etc.,

A. J. BOASE,
Ophthalmic Specialist, Colonial
Medical Service
Mulago Hospital, Kampala, Uganda

Loss of Vision following Haemorrhage

SIR,—I venture to submit the following notes based on a study of the literature and on my own small experience. It is rare for any individual to have experience of more than one or two cases.

Instances were recorded in young men in the 1914-18 war (Pincus, 1918), and Tidy has stated that "no age is immune."

Papilloedema in some degree is probably present in nearly every case, but may be missed if the examination is not made at an early stage.

Narrowing of the retinal arteries is inconstant and not uniform. The continuation of the affected vessels does not accord with the blind areas in the visual fields as it does in cases of occlusion of a branch of a retinal artery. The type of narrowing is not the same as that present in elderly people who have diseased arteries. Narrowing of the arteries is probably a sequel rather than the cause of the condition.

Cases characterized by central scotoma with little or no peripheral field change have been reported, and, presuming the observation to be correct, suggest a lesion of the retinal ganglion cells or of the macular fibres—a view advocated by Holden. The clinical course of the disease, its signs and symptoms, regarded as a whole suggest the action of a nerve poison rather than a vascular disturbance.

Apart from the work of Holden little, if any, research appears to have been undertaken. Holden bled dogs and found degeneration of the retinal ganglion cells. Mayou reported a case of a dog which became blind after severe haemorrhage from the intestine. Thorough perimetric examination undertaken as early as possible might throw some light on the nature of the condition.

Tidy's treatment by transfusion, liver, and iron seems very plausible, but requires confirmation.

An extensive literature exists. A good account of the condition is given by Groenouw. I append several references not mentioned in the recent correspondence. The condition was apparently known to Hippocrates—I am, etc.,

Juvenile Delinquency and its Remedy

SIR,—The views expressed by Dr. R. H. Ahrenfeldt (Feb. 2, p. 216) concerning the fallacies of statistics relating to juvenile delinquency are undoubtedly sound, but one must question the wisdom of emphasizing, except in theoretical discussion, that the roots of later antisocial actions are deep-seated in the unconscious mind and far back in childhood. Everyone who works in psychiatric clinics for children knows that there are very many cases of theft, breaking and entering, wandering, and malicious damage which never reach official cognizance, and a great many more are undiscovered. So it is that the statistics are misleading.

Juvenile delinquency arises in most cases from one direct cause or a combination of several direct causes. Children who are backward educationally become frustrated with hopelessness bred of constant failure, and may indulge in truancy, with all its temptations to escape from it, or adopt some wild behaviour to gain compensation in notoriety. Broken homes or warring parents fail to give children emotional security or discipline or even normal family interests and occupations, and the resulting vague disturbances of peace of mind may cause a child, untrammelled by control and ordinary ethical standards and with time heavy on his hands, to try to square things up by taking things from others, maybe his more favoured brethren,

or even drive him to run away from the conditions that are disturbing to him. The number of cases where delinquency depends on specific mental illness is negligible, and then the trouble is usually obvious.

Psychiatric theory applied to delinquency can explain the deeper mechanisms which are operative in it, but it does not excuse the misdeeds nor help in the practical solution of the problem. Its application has, in fact, hindered progress, creating the erroneous belief that the whole matter is so deep and delicate that no direct methods to deal with it should ever be tried. This has given free rein to those who hold that crime is a mental disorder, and inhibited the common sense in their efforts to do something about it. Juvenile delinquency will persist until it is recognized that children gain stability and security from work, control, and discipline, and that these can be applied as well as understanding and correction of the underlying causes of the unacceptable behaviour.—I am, etc.,

WILLIAM MOODIE.

Homosexuality

SIR,—The letter of Mr. D. Stanley-Jones (Feb. 2, p. 179) reflects very adequately the views of medical men who have knowledge of patients afflicted with sexual inversion. It would, however, be rash to assume that all homosexuals are to be pitied. Many are untreatable by psychological methods, because they disdain treatment or seek it only when faced by lowly social complications. Homosexuals of this type are proud of their condition and regard themselves as of superior quality to those whose sexual instincts are normally directed. The size of this group is unknown, as only a few from it seek medical advice. But, in addition, there are very many homosexuals who do realize their abnormal state, regret it, and long for release from it. Some of these can be cured, and others can be helped to make a satisfactory adjustment to life.

The estimate of 2% of the population made by Havelock Ellis is probably an intelligent guess; there are no figures on which such a calculation might be based. The number of homosexuals is high and may well be more than 2% of the population.

From time to time these unfortunate people come into the hands of the police. The working of the legal machine is by no means uniform. The wisdom or discretion of judges and magistrates shows much variation. On occasions I have appeared as an expert witness when a homosexual had come for trial. My experience has been on the whole favourable, and I have been impressed by the broad-minded attitude of certain judges and magistrates who, on hearing medical evidence, have put the prisoner on probation. This, of course, has not always followed.

In many instances, presumably, no medical evidence is called. Within the last few months severe sentences have been passed on persons found guilty of homosexual practices. Mr. Stanley-Jones refers to one such case. Another example is the sentence recently passed upon an Edinburgh schoolmaster. The protection of the public is apparently a chief consideration in the mind of the judge who passes sentence. This is clearly important, but it can be over-emphasized. I have, from time to time, seen the "victims" of homosexual practices, and the psychological trauma from which the occupants of the Bench consider they must suffer has been absent. The incident had made little or no adverse impression on the youth, as an adjustment had been made to it. To protect a youth from such an experience is very important; but the normal boy will not be blighted for life if he is unfortunate enough to have been on terms of sexual intimacy with a homosexual man. There are other factors in such relationships; and the sexual activity may play a minor part in a friendship which often has in it much of value.

It is true that the medical profession is largely uninformed about sexual perversions. But ignorance is less widespread in the younger generation. In certain medical schools systematic lectures on the psychoneuroses are given in the clinical years, and teaching on sexual abnormalities is included in these. Much remains to be done. Such lectures should be in the curriculum of every medical school. Similar courses of lectures for general practitioners were given regularly in various centres in London before the war and are being resumed. Before we condemn

the obscurantism of the legal profession we must set our own house in order. Some judges are not swayed by medical opinion even when it is available. Their interpretation of the law is their only guide. It is time, therefore, to amend the law so that they may be freed from the compunction which may well arise in the administration of a code condemned by informed opinion.—I am, etc.,

London, W.1.

E. A. BENNET.

SIR,—I was much interested in Mr. D. Stanley-Jones's most eloquent letter (Feb. 2, p. 179). Now that this subject has been opened in your columns I hope that it will be ventilated more fully by authorities better qualified than I.

I have no claim to write as a psychologist, but as a venereologist I am frequently called on to advise on various aspects of sex, including homosexuality or inversion. Many of my invert patients have been treated, some of them for prolonged periods, by medical psychologists with complete absence of success. From my own impressions and from what I have read, I think one must distinguish between genuine inversion, almost certainly a congenital condition, and those who have, as the result of certain circumstances, temporarily acquired the habit of homosexual practices. I believe that it is this latter type of case that may be benefited by psychotherapy. With inversion there appears to be an inborn unwillingness to be cured. In such a case I should imagine that it would be as difficult to achieve a reversal of the sexual aim as it would be in a heterosexual—i.e., normal—subject.

In the pathetic case mentioned by Mr. Stanley-Jones surely the man was being punished not so much for his homosexuality as for his lamentable absence of control. Offences against little girls, equally or even more common, are in a similar category. Distressing as it is, I cannot help feeling that psychological treatment would be quite hopeless in a man of his age and record. Society must protect its children to the best of its ability. I do not see any alternative in this particular case.

I feel sure that Mr. Stanley-Jones is in general mistaken about the "ignorance of sexual abnormalities" in the Prison Medical Service, and I think that if this unfortunate man shows any desire to co-operate, all that is possible in the way of psychological approach will be done.—I am, etc.,

London, N.W.8.

F. G. MACDONALD.

SIR,—I would like to support the protest uttered by Mr. Stanley-Jones against the sentence of fourteen years' imprisonment recently meted out to a scoutmaster convicted of immoral conduct with boys. It is true that the law lags some fifty years behind public opinion and that the public has not yet realized that the homosexual is not himself responsible for his inversion, that the medical profession cannot be held entirely guiltless if, with more knowledge, it accepts the Law's method of dealing with such cases. Minors of both sexes must be protected against sexual assault, but the Law's "treatment" of homosexuality is an anachronism in an age which recognizes that it is sometimes amenable to suitable medical measures. Is it not giving the Law our approval when we remain silent?—I am, etc.,

London, W.1.

KENNETH WALKER.

SIR,—In view of Mr. D. Stanley-Jones's letter I am writing to call attention to a resolution passed at the recent annual general meeting of the Prison Reform Council, in case it might be of interest to your readers:

"Resolution 2: This meeting records its opinion that the present arrangements for dealing with persons convicted of homosexual offences, sexual malpractices, and assaults and similar offences, are inadequate and deplorable, and asks that whilst the present practice of committing to prison is followed, the best possible psychological treatment should there be available, and calls for a change in the law whereby such offenders shall no longer be sent to prison but placed—where necessary—under more suitable restraint."

In dealing with such cases there appear to be two lines of approach: (1) preventive, (2) curative. Under the former heading the early environment must be studied, for there is much evidence that sexual malpractice (e.g., homosexuality) is mostly acquired and is the outward and visible sign of inward emotional disturbances generated by unfortunate early environ-

ments. Frequently the parents have wanted a girl rather than a boy, and as the boy grows up he is over-indulged—a tendency in parents towards an unwanted child. In addition, perhaps his hair is kept too long and his garments in early life are more feminine than masculine; habits of cleanliness are enforced too rigidly and too early, while that amount of roughness and independence so wholesome for the developing male is checked, and in its stead dependence is encouraged, with the development of "the mother's boy." Early protests to such handling become generated in the boy and repressed. The thinly disguised wish of the parents for a girl may result in the boy becoming a resentful caricature of one.

Another frequent cause of early difficulty is found in the child that is brought into too close proximity when young with adult sexuality. It is even found to be unwise to let children share the parents' bedroom, for precocious looking is stimulated. The wiser parent will arrange for his child, whether male or female, to have its own room—perhaps opening off that of the parents.

During the first six years of life it is wise for parents to abstain from manifesting undue interest in the child's anal activities. They should avoid stimulating the child's erotic zone, either directly or indirectly, for such stimulation may predispose the child towards imitation and repetition, with the perpetuation of unnatural practices. Therefore, unless it is absolutely necessary for the child's health, it is wise to avoid (a) rectal examination, (b) an enema, (c) a suppository. In other words, the adult should do nothing that could be construed by the child as a "rape," or breaking into his "house." Such treatment, however well meant, can only foster those suspicions of an adult and incite fear, for such suspicions reside in the mind of every child. Confidence in adults is acquired and never innate.

To overcome any such fear that may have been aroused, the child tends to become subsequently too passive. It may offer its own house or body to be broken into. The child may then grow up to become a solicitor—that is, if male the passive homosexual, and if female the prostitute. Alternatively, if such a man be of a more vindictive turn of mind, he may develop retaliatory habits and become the house-breaker or the raping adult who may even sexually assault children of the age that he was when he was (as he felt it) "assaulted."

Should prevention fail, the only efficacious treatment to my mind is psycho-analysis, but the individual must wish for this, and it is useless if carried out under duress. Such treatment has the advantage that the patient can carry on with his ordinary work, coupled with daily visits to his analyst. Opportunities are provided in the treatment for the liberation of those affects and emotions that have hitherto been pent up—such affects due to all those early interferences that have preceded the formation of his perversions. Only then is there a chance of such propensities becoming diminished and even ultimately disappearing. The earlier in age such treatment can be carried out the easier it will be. After being a short time under treatment the patient is more easily able to control his tendencies so that they are kept within bounds and at any rate no longer obtrude upon a disgusted public. Later on, as Mr. Stanley-Jones has stated, they may be able to be given up entirely, though naturally this must largely depend upon how strong is the wish in the patient to be cured, how early in life the provocative stimulus was aroused, and if the patient can continue his treatment for a sufficiently long period.

An interesting commentary on the Law's approach to such matters is provided by the fact that where it takes little or no notice—as in the case of female homosexuality—it tends not to obtrude itself unduly upon the notice of the public, whereas in the case of male homosexuality, about which matter the Law has tended to become over-zealous in its attempt to stamp out such practices, they flourish and indeed become more and more insistent. So far from showing signs of diminishing, it appears to be on the increase. It is only necessary to visit any public lavatory in this metropolis to observe how numerous such practices must be—what with the writings on the walls, holes bored in lavatory doors, etc. The very recent case of a scoutmaster sentenced to fourteen years for certain serious offences against four boys in his troop, referred to by Mr. Stanley-Jones, is a case in point. He had had two previous convictions, one in 1922 and another in 1932, and so far as one can gather he had had no psychological treatment for his obsession.

It must be remembered that anyway the homosexual is a rebel. The more you try to excommunicate a rebel the more of a rebel does he behave. The Law as at present constituted makes two cardinal errors at least, to my mind, in its handling of this matter: (1) It obliges the homosexual's (unspoken) request for a homosexual environment by sending him to prison, segregated from the opposite sex. (2) It obliges the homosexual's craving for notoriety (exhibitionism), first by the spying and watching needed for the police to take action; secondly, by the committal, prosecution, and trial that must follow. Homosexuality is kept alive by such treatment. The prisoner is discharged after a long or short sentence, remaining still the homosexual but now one with a grievance, and so the blackmailing type may result.

Unnatural offences are not to be satisfactorily dealt with by the attempted forcible restraint of the offender in a strictly unnatural (i.e., homosexual) and artificial environment such as prison provide. Even were psychological treatment to be provided for such a one (which it is not), it is doubtful whether such an environment would not work against a successful outcome. Success in psychotherapy depends so much on the voluntary nature of the treatment; it cannot be carried out under duress. The public naturally must be protected, but prison seems hardly the ideal way to achieve this—I am, etc.

London W

A CYRIL WILSON

SIR,—May I, as a psychiatrist and a practising psychotherapist, add my own profoundly indignant protest to that of Mr Stanley-Jones against the sentence of fourteen years' penal servitude passed on a scoutmaster recently.

It should be possible—and I shall be the first to join forces—to make psychiatry's weight felt against the passing of such judgments. I possess records of other such cases, none, however, so ghastly in their severity as this one and I shall welcome any further data any of your readers may care to send me or the subject.

I should also be grateful to receive the co-operation of psychiatrists, preferably those who, like myself, are uncompromisingly heterosexual, in order that concerted action may be taken towards a modification of existing laws—I am, etc.

A Wood House, Kingswinford, Staffs

WM A O'CONNOR

SIR,—Mr. D. Stanley-Jones's letter (Feb. 2, p. 179) must have been a shock to those readers who complacently assumed that law and medicine advanced side by side in these enlightened times and learned judges eagerly sought the advice of psychiatrists in appropriate cases. The sentence of fourteen years' penal servitude for homosexuality takes one back to the days when people of sound mind were put in chains. Is there no medico-legal organization to protect psychopathological cases such as this from out-of-date laws and direct the sufferer to the proper channels of treatment?

When the husband of one of my patients was summoned for indecent exposure I made strong representations to the defending solicitor, who was able to persuade the stipendiary magistrate to await the examination of the patient (accused) by an eminent local psychiatrist. As a result of the latter's findings the man was bound over on condition he attended the specialist for treatment. This he did until a cure was effected.—I am, etc.,

Hull

L. I. HARDY

"Cord Round the Neck"

SIR,—The stupendous total of 5,000 confinements attended by Dr Robert Anderson (Feb. 9, p. 219) with no stillbirths which he could ascribe to the common obstetric finding of cord round the neck seem most remarkable, and should, no doubt, scotch the obstetric superstition! (Mr. Mortimer Reddington, Jan 19 p. 109) under which we have, shall I say, sheltered for so many years.

In the past twenty-four years I suppose I have attended a mere 500 cases if as many, and I seem to remember not a few in which the cause of the stillbirth appeared to be "cord round the neck." Two cases come to my mind.

The first was a lady in her thirty-eighth week, who, in the absence of disease or trauma, had a sudden concealed haemorrhage. Delivery took place a few days later. The stillborn child had a very tight short cord wound round its neck, and the placenta showed a central area which obviously had been dragged away from the uterus

with the short cord some days previously. I take it that the descent of the head into the pelvis gave the final tug that pulled the centre of the placenta away from its site.

The second case had a happier ending. A middle-aged lady, who had lost her first baby in childbirth and who was desperately anxious not to lose her second, was found to be a breech. This I turned by external version on more than one occasion, but back the baby turned *almo* immediately. There seemed to be an elastic "something" that pulled the head out of its proper position. I made the provisional diagnosis of a short cord wound round the neck, and sent the case to Prof. English in Singapore, asking for a "Caesarian" to be done to ensure a live birth. Thus he did, and confirmed the diagnosis at operation, and produced a live child. Had this case been allowed to go into labour as a vertex I am certain that the child would have been stillborn and the cause again would have been "cord round the neck."

I should like, however, to read further opinions from men better qualified than I to express them, and I hope they will find time to give us the benefit of their views—I am, etc.

Edinburgh

I. G. CAMERON

Predisposing Factors in Carcinoma of the Cervix Uteri

SIR,—I think that your correspondent Dr Nettleton (Feb. 2, p. 182) must have misunderstood Mr. Carnac Rivett. It is well known that carcinoma of the cervix does occur in nulliparous women. The late Dr. Horden stated in his book that of the cases admitted to the Marie Curie Hospital 134—i.e., 10.4%—were in nulliparous women. G. Ward gives the figure of 12%: the figure at Mount Vernon Hospital is 8%. Your correspondent will find some interesting observations by Dr. Percy Stocks on this subject in the British Empire Cancer Campaign Annual Report for 1941. Of 800 cases of cancer of the cervix, 11.3% occurred in nulliparous women. These figures were obtained from the statistical survey carried out by the Clinical Cancer Research Committee.

Personally I consider that the trauma due to confinement is very unlikely to be a major factor in the aetiology of this disease—I am, etc.

LEEDS W

MALCOLM DONALDSON

Self-medication in Midwifery

SIR,—The methods for the relief of pain in labour which have appeared recently in this *Journal* depend for their success on the presence of doctor or nurse. For several years it has been my routine practice to leave with the patient at the antenatal examination four capsules of nembutal gr 1½ (97 mg). The patient is instructed to take all the capsules as soon as the pains occur at ten-minute intervals. There has never been the slightest sign of overdosage in mother or child. In fact it is usually necessary to supplement the nembutal with some other medication, for which my personal preference is hyoscine. Probably this method is widely used already. It has the great advantage of reassuring the patient, who knows she is not entirely dependent on outside sources for the relief of pain—I am, etc.,

Norfolk

J. N. GALE

Tuberculosis in Childhood

SIR,—The controversy which has arisen on this subject (Feb. 2, p. 180) is unfortunate. Surely the tragedies of juvenile tuberculosis should not be the battleground of two diametrically opposed opinions. Whatever the real incidence of infection with the tubercle bacillus in infancy and childhood may be, the fact remains that in regard to the individual case no one can say with any certainty what will ensue. We know something of the life history of the infection, and we know that Nature is, in many cases, kind and curative, but it would be most unfortunate if the profession and the public should gain the impression that tuberculous infection in children is of no real significance. Even if there have been "for a number of years" fewer than 2,000 cases of tuberculous meningitis, this cannot in the minds of physicians, be regarded without concern. I would perhaps be much more pertinent to try to inquire more precisely why some cases generalize and produce this fatal outcome rather than accept it fatalistically. Also, do we know how many babies and young children die with unsuspected tuberculous bronchopneumonia or military tuberculosis? What should some of us strive to ensure a tubercle-free milk supply?

if, on the other hand, we say that the more common aerogenous infection does not really matter? I am sure paediatricians do not wish to overweight the importance of this, but they cannot close their eyes to something which can be bettered. Surely the answer is not complacently to suggest that "such children appear to be like guinea-pigs in whom the disease follows an inevitable course," but to pool effort, resources, and interest, in expounding by gentle persuasive tactics, without undue alarm, the preventive principles so admirably stressed in Prof. Moncrieff's lecture.

Statistics may give a sense of relief, but to the consulting physician and family physician they may not operate so convincingly. One must grant the deepest sympathy to the phthisiologists in their overwhelming tasks, but a good winning team calls for a stubborn defensive line as well as lively thrustful forwards.—I am, etc.,

Birmingham.

A. V. NEALE.

SIR,—My plea was for the routine tuberculin testing of children and for the separation of the positive reactors under the age of 2 years from cases of open tuberculosis.

We are all agreed that primary tuberculosis in *childhood* is usually benign, but unfortunately in *infancy* such is not the case. Routine testing of infants would surely bring to light many unsuspected cases of adult phthisis in home contacts, and it would also help materially to diminish the number of deaths from tuberculous meningitis.

Dr. Hall is wrong in assuming that I advocate spending time, energy, and money on cases showing only a positive Mantoux; I do no such thing. He is also wrong in saying that first infection is almost always innocuous. In infancy it is fraught with grave danger, and the sooner this is generally appreciated the better.

Dr. Orpwood asks how it is that individual paediatricians see scores of infants dying from tuberculous meningitis. It is, alas, because there are such scores of infants who die from it (nearly a hundred score every year, according to his figures). In the last twenty years I myself have certainly seen scores, and I make no claim to any special experience of this condition not shared by other paediatricians.—I am, etc.,

Warwick.

WILFRID F. GAISFORD.

Effect of Blast on the Human Ear

SIR,—I have read with interest the article by Major F. B. Korkis on the effects of blast on the human ear (Feb. 9, p. 198). My experience in Italy has been much the same as his. In 1944, out of 3,296 new cases examined 344 (10.4%) were patients suffering from the effects of blast. Of these, 101 had a concussion deafness with normal drums; 50 showed drum congestion and haemorrhage; 115 revealed traumatic perforation, unilateral or bilateral; and the remaining 78 suffered from traumatic otitis media. All were treated to recovery, and only seven cases required mastoidectomy.

Major Korkis was indeed fortunate in having a full set of tuning forks and an audiometer with which to test his patients. The British otologist, unless he carried his own instruments, was provided with only two forks, 256 and 512 d.v.s. Indeed, it was only after the collapse in North Africa that I was issued with a 4,096 d.v.s. fork and thus was able, with some accuracy, to test for concussion deafness. A patient who has been in action and who, with a positive Rinne, cannot hear a 4,096 tuning fork is suffering from concussion deafness.

Two of the conclusions reached by Major Korkis are of more idealistic than practical value. I do not think it possible to review every six months the ears of those exposed to blast. I was attached for over two years to the hospital which served the Royal Artillery Training Depot and can assure Major Korkis that the population of the depot was constantly changing and was always numbered in the thousands. To have attempted such an investigation would have been impossible. Furthermore, on British classification of medical categories it was not possible to ensure that a man would be kept off the guns. One could not qualify a medical category in the C.M.F., and could only make recommendations to the medical officer of his unit. Records Office, who did the postings, relied solely on the actual category. Nor, from the man-power situation, could one in

all honesty make the men C1 (base duties only), as no replacements were possible and the men were physically fit and anxious to return to their old units.

The other conclusion of Major Korkis with which I cannot agree is the suggestion that all men under the age of 40 should have a routine audiometry. This is impossible on two scores. In the first place, there are no Army audiometers in this country. Secondly, the Government is at present releasing 100,000 Service personnel weekly. Who is to undertake this routine audiometry? There are thirteen British Army otologists in the U.K. at present, so each would have to do nearly 8,000 audiograms every week. Or does Major Korkis intend the civilian otologists to help? In that case, on the assumption that there are 300 otologists in the country, each would have to carry out over 300 routine investigations in addition to his normal week's work.—I am, etc.,

J. F. BIRRELL,
Lt.-Col., R.A.M.C.;
Adviser in Otology to U.K.

London, S.W.1.

Stethoscope versus X Rays

SIR,—As one who has interpreted between 20,000 and 30,000 chest skiagrams, mainly of patients previously examined by myself clinically, I should be the last to dispute the undoubted fact that in the vast majority of instances x rays give a more accurate picture of the localization and probable nature of any lesion present than do the clinical findings. However, there are cases where abnormal clinical signs can be found prior to the appearance of any shadow on the film, and the abandonment of the use of the four senses in favour of one only would in these cases be disastrous for the patients concerned and damaging to the reputation of our profession.

I am sure that most clinicians with extensive experience in the diagnosis of chest disease must have come across the patient who is referred for an opinion because of toxic symptoms, evening temperature, lassitude, weight loss, and occasional dry cough, where, on clinical examination, the findings are increased muscle tone over one upper zone with resulting diminution in movement and weakening of the respiratory murmur, and where the film, taken with an efficient and up-to-date x-ray apparatus, fails to reveal any abnormal shadow. If one's clinical acumen brings about a realization that the patient is ill he is kept under observation, when a further film in a few weeks' time will reveal an early tuberculous lesion at the site of the abnormal signs. If not, and the patient is regarded as non-tuberculous, he returns sooner or later with his disease in a more or less advanced stage. Such cases are admittedly rare, but I can myself remember at least half a dozen in the course of fifteen years' work. The only explanation I can offer for the failure of the x-ray to demonstrate the condition is that the disease is so early that sufficient exudate has not developed to create a demonstrable shadow. This explanation is supported by the fact that cases of generalized miliary disease frequently fail to show any lung abnormality on x-ray examination in the early stages of the illness.

More important even than early tuberculosis and much more frequently missed on x-ray examination is the early neoplasm, before the tumour has passed beyond the confines of the bronchus or brought about sufficient occlusion of it to produce a degree of collapse which can be noted on a skiagram. The patient is usually referred because of one or more of the symptoms—dyspnoea, pain, and haemoptysis; and physical signs in the way of slight localized impairment of movement and diminution and alteration in the tone of the breath sounds with prolongation of expiration should dictate bronchoscopy, despite negative x-ray findings. More than one operable tumour has been brought to light in my experience where physical signs alone gave any indication of its presence.

In chest examination, therefore, we must still continue to use all our senses, except that of taste, and the employment of all projections of them which can help us, be they x rays, stethoscopes, or bronchoscopes, must continue to be taught and well taught. Here I would put in a plea for using the early case for teaching purposes, so that the finer shades in physical signs may come to be learned as well as the gross manifestations of well-established disease conditions.—I am, etc.,

Leicester.

A. SCOTT,
Tuberculosis Medical Officer.

mon usage and would not be easy to memorize. For example, nobody prescribes 16 mg. morphine (1/4 gr.) on the Continent, but either 0.01 g. or 0.02 g. (or, if you like, 10 and 20 mg.). Again, in your issue of Jan. 12 (p. 74) you give the prescription of an alkaline draught: sod. chlor. and sod. bicarb. āā gr. 15 (1 g.) in 2 oz. (56 c.cm.) of warm water (because the British practitioner is used in prescribing in table- and tea-spoonful doses). It must be hard to memorize just 56 c.cm. The usual way in the metric system is to prescribe amounts of, say, 250 or 300 c.cm. and not 224 or 336 c.cm. (8 oz. or 12 oz.), etc. The man educated in the metric system either prescribes—in the case of powders—a single dose and remarks: T.D. No. X (so many doses, send ten) or—in the case of liquids—he multiplies the single dose, e.g., with 25 and prescribes: sod. chlor. and sod. bicarb. āā 25 g., aquam ad 600 c.cm.; signa: 4 table-spoons t.d.s.; or he will probably prescribe sod. chlor. and sod. bicarb. āā 25 g. aquam ad 300 c.cm.; signa: 2 table-spoons t.d.s. in water. I am aware that 24 table-spoons are not exactly 300 c.cm., but 1 oz. is not exactly 28 c.cm. and also 1/4 gr. is not exactly 16 mg. Unless the familiar or usual prescription in the metric system is put parenthetically to the apothecaries' one, the metric system cannot be made popular with the British practitioner or student.

Further, I would suggest that the term ml., which is not in general usage on the Continent, should be dropped, and c.cm. used exclusively instead. This must of necessity confuse the medical man abroad, which fact does not help to achieve the goal originally aimed for.—I am, etc.,

Cambridge.

ALBERT W. BAUER.

The G.P. and Hospital Practice

SIR,—Many hospitals are now being released from military service and restored to civilian use. Now is the time when, in their reorganization, far-seeing hospital authorities could ensure that co-operation of practitioners with hospitals about which we read so much and so far have little opportunity of seeing put into effect. It is a fact at the moment that the general practitioner is completely excluded from the wards in most of these hospitals; and while I appreciate the difficulties that might arise in administration, with 20 doctors responsible for their own beds, I think this could be overcome in the same way that it was overcome in America by the Permanente Foundation in San Francisco (Garfield, S., *J. Amer. med. Ass.*, Oct. 7, 1944, p. 337).

My suggestion is that the consultants of these hospitals should invite local practitioners to do a ward round with them once or twice a week. Thus the practitioner would have the opportunity of maintaining contact with both his patient and with the latest medical teaching. The consultant would still be in charge, from the point of view of administration, and I would also suggest, with respect, might learn a little, too, from his colleagues. The complete divorce which now exists between patient and general practitioner when once the former enters hospital can thus be overcome with mutual benefit. I would recommend hospital authorities not only to study this question but to bring about a speedy solution in actual practice.—I am, etc.,

Urmston, Lancs.

BERNARD SANDLER.

Diagnostic Acumen of the G.P.

SIR,—Is it not possible to alter the tone of this discussion, which, if memory serves, began with diagnosis of cancer of the breast? Should early cancer be referred to, the problem is admittedly not easy; indeed, it is frequently solved by a biopsy or, alternatively, the removal of a non-cancerous breast by the distinguished specialist.

The errors of the G.P. have been pilloried, and it would be easy to produce a list of mistakes by very eminent surgeons and gynaecologists. I could supply a few, even, on occasion, made against the advice of the attending practitioner. *Cui bono?* Surely the moral is that we all approach our work with some sense of responsibility and proportion, and that we remember that consultation with, not merely listening to the *obiter dicta* of, trained and skilled specialists will often be in the best interests of all.

May I suggest to Mr. Deitch (Feb. 2, p. 183) that failure to give weight to rising blood pressure and oedema does not in these days argue a very competent practitioner, even if one reads in Munro Kerr's recent *Obstetrics and Gynaecology* on toxæmia: "Even to-day the subject is teeming with opinions and theories."

The day may come when everyone will be referred to the appropriate specialist by a sorting clerk, who could in no sense of the term be called a general practitioner. Till then should we not realize that there is no closed monopoly of intelligence and that mutual recrimination or one-sided slanging does not make for the dignity of our profession or the advance of our art?—I am, etc.,

Southport.

W. A. MACKAY.

SIR,—Every G.P. of reasonable competence has a right to fulminate against ill-considered and libellous indictments such as the misstatement that "the general practitioner . . . is a careless and poorly equipped accoucheur, a positive danger to any lying-in woman, and should on no account attend a mid-wifery case" (Jan. 12, Feb. 2, etc.). This may apply to some G.P.s, but certainly not to general practitioners as a whole.

What G.P. of tolerance born of experience would make the counter-charge that no lying-in woman should ever be attended in an institution because cases are on record where sepsis has been spread round a ward to other lying-in women from an infected case? Or because mothers have been sent home from nursing homes with breast abscess, or sent home with the wrong baby owing to errors in labelling newborn infants in mass-production centres?

Mr. H. I. Deitch (Feb. 2, p. 183) quotes the occasional tragedy seen in hospitals. He appears to forget from his calm sequestered heights that the hospital obstetrician sees more of abnormal than of the normal confinements ably performed throughout the length and breadth of the realm, including rural areas and the Outer Hebrides, and suggests that it is stubborn not to realize that obstetrics is a special art to be performed only by those with special knowledge and experience. Are obstetric specialists born experienced? He quotes a case where forceps were applied outside the os—a heinous offence, all will agree. May one ask who taught the offender, examined him, and passed him fit to practise on a trusting public?—Obstetric specialists of repute. Are we justified in stating, therefore, that no obstetrician should be allowed to teach or examine in obstetrics? We should be no more justified than are the few obstetricians who cite the errors of "black sheep."

Suppose that we took the cranks at their word. Are there enough obstetric beds to accommodate all normal as well as abnormal confinements? No! Would the great men attend the normal cases themselves, or would the labour-ward sisters do the work and act as G.P.s, calling for assistance if a case presumed normal on examination proved difficult in labour? Why should expectant mothers who are physically normal be turned into physiologically and psychologically abnormal cases through fear engendered by the views of unbalanced obstetrical extremists? With Mr. Bevan making a frontal attack on the whole medical edifice it seems sad that some of the exalted chimney-pots should revile the foundation-stones of the obstetrical wing and tell them that they are a positive danger.—I am, etc.,

Norfolk.

E. PUDDY.

SIR,—From their lofty heights our specialists and consultants are rather too fond of castigating the inefficient G.P., and demanding that this and that branch of medical work shall be taken from him, because of his gross errors. Do they never reflect that they only see the occasional mistake, and that the mass of good work done passes by them unnoticed? And do they never say, "There, but for the grace of God, go I"? Some years ago a very eminent paediatrician saw a patient of mine and diagnosed "suppressed whooping-cough." The child eventually turned out to have an abscess in the hip-joint. More recently I sent a woman to hospital to have a colporrhaphy, and she was returned to me with her appendix neatly removed. The fact is that all doctors are human and we all make mistakes. Let us try to correct our mistakes by all means, but let us sling a little less mutual mud in the process.—I am, etc.,

Ashted, Surrey.

W. EDWARDS.

Motive in Medical Demobilization

SIR—Sir Ernest Graham Little's letter (Feb 2, p 23), in which he suggests that the motive for the recent large demobilization of doctors is the desire of the Government to flood the medical market and to force us into a State service will be deeply resented by many of those who are lucky enough to be demobilized under this scheme. A less biased opinion might have come to the more obvious conclusion that, if the Government had this ulterior motive in view, it would have been to its advantage to hold up such a large demobilization until the summer, when it would have been extremely difficult to absorb so many men into medical activities. But just the reverse seems to have happened, for it is well known that for some months the Government has been pressing for the speedier release of medical men. This was no sudden decision, as Sir Ernest suggests, and if transport and other service difficulties could have been overcome the present mass demobilization would have taken place earlier in the winter. However, better late than never, most of us will find plenty of work awaiting us and we shall leave it to Sir Ernest to rumble that whatever the Government does is wrong.

The needs of civilian medicine have been stressed often enough in recent months. Surely it is more reasonable to assume that the Government decision was made in the interests of civilian patients and overworked civilian doctors than to consider it a piece of political chicanery. Why look for a dirty motive when there is an honest one staring you in the face?—I am, etc.,

Eastbourne

H G ESTCOURT

A Fundamental Principle

SIR—The letters in the *Journal* of Feb 2 (p 185), under the heading "A Fundamental Principle," were there to be widely circulated in the daily press, could only convince the State or community (I use the terms in the sense Dr Eastwood understands them) that the medical profession is, in so far as the writers of these letters are representative of it, entirely selfish and unconcerned for the welfare of humanity as a whole. It is unfortunately only too obvious that so long as there is a shortage of doctors there will be a tendency—natural, I admit, however deplorable—for the poorer, dirtier, and therefore more needy areas to suffer from lack of adequate medical care. This tendency is inevitable, human nature being what it is and the situation can be met only by a planned medical service whereby an adequate number of doctors are directed to the needy areas. Had the profession as a whole in its discussion of the State medical service question showed some real concern for the welfare of the people, as opposed to that of the doctors one might have hoped for a natural or spontaneous cure of this great medico-social malady. It is our own fault that the Government is about to take the cure out of our hands, and we cannot blame it.

I should be the last to suggest that direction should be unlimited, but surely direction of young doctors, say under 30, with some temporary discomfort and loss of freedom, is a small sacrifice to pay, albeit a vicarious one for the betterment of the health of our large industrial communities. Dr Eastwood suggests that the State or community is about to exploit us for their own benefit just as "slaves are exploited." Surely this "noble" profession of ours, with all its culture, learning and wide experience of life, could never become "enslaved" merely because its work was ordered or its members directed.

I venture to suggest that in accepting a full time salaried State medical service even though it may bring some restrictions on our professional or personal liberty, we shall be emancipated rather than enslaved. In the past many of us have been literally in bondage with our practices mortgaged and with day-in-day-out competition often against unscrupulous "colleagues" whose financial position is more satisfactory than their medical ethics or their knowledge of medicine. I would submit that for the young doctor direction for a year or two to an "undesirable" industrial area would prove much less soul-destroying than the present, often unfair, competition that is inevitable under the profit-motive system.

hope there may be enough leaven in it to "leaven the whole lump," and I trust you will show impartiality in publishing this letter in the *Journal*—I am, etc.,

Glasgow

JOHN H WILSON

Principles IV and V

SIR—I cannot believe that those who crafted the seven principles intended Principles IV and V to be taken seriously. Principle V is read first and then IV and are as follows:

"V. Every registered medical practitioner should be encouraged as much as possible to participate in the public service."

"IV. Doctors should, like other workers, be free to choose their form, place, and type of work they prefer without Government or other direction."

This would seem to mean that every doctor would have the right to demand an appointment in the public service in whatever type of work he preferred and in any place he chose. Should all the doctors in Sheffield wish for example, to work in Bournemouth—a not unreasonable desire from some points of view—the Minister of Health would be bound to accede to that end if Principles IV and V are to be observed—I am, etc.,

Sheffield

JOHN PENNIFORT

Medical Future of the Colonies

SIR—Many of those who have served in tropical Africa are in full sympathy with the desire of Colonials to take an increasing share in the public services of those Colonies. But when your correspondents ("A Colonial," Jan. 26, p 147, and Dr Eastman, Feb 9, p 219) claim equal conditions of employment for Colonials and Europeans they ignore important issues.

The salary scales leave provision, etc., for Europeans have been drawn up with due regard to the fact that these officers serve in a climate highly inimical to them and far distant from their homes. Their emoluments may properly be considered a compound of a basic rate augmented to compensate for these drawbacks. In the case of the British Army, officers paid £1,000 a year are doubled while serving in West Africa. Colonial officers can scarcely expect to be compensated for disabilities from which in fact they do not suffer.

And looking forward to the day when these Colonials will manage their own affairs a grave disservice would be done them by leaving a legacy of officials remunerated on a scale having no relationship to the economic status of the community for whose benefit—in democratic countries at least—their services are required—I am, etc.,

B. Easton

J B DAVEN

The Disabled Person

SIR—Dr J S Laurie (Feb 2, p 183) refers to difficulties in the issue of certificates under the Disabled Persons (Employment) Act, 1944. While as he says every case must be treated on its merits there are certain points which make it quite easy to decide whether a certificate should be granted in any particular instance.

First, there is the statutory definition of disabled person. "The expression 'disabled person' means a person who, on account of injury, disease or congenital deformity, is substantially handicapped in obtaining or keeping employment, or in undertaking work on his own account of a kind which affords that injury, disease or deformity would be suited to his age, experience and qualifications; and the expression 'disablement' in relation to any person shall be construed accordingly. The expression 'disease' shall be construed as including a physical or mental condition arising from imperfect development of any organ." The meaning of "substantially handicapped" is made quite clear by the Minister. "The criterion of any applicant is the effect of the disability on his prospects of employment in comparison with those of a person of similar age, experience, and qualifications who is not so disabled as who is employed in or is an applicant for the same or a similar kind of employment." The Minister has also stated that borderline cases a reasonable and generous view should be taken.

The Minister Listens

SIR,—Like countless others I have been waiting for many weeks for some hint as to how the negotiations were proceeding between the Minister and the Negotiating Committee. The answer comes in your leading article (Feb. 16, p. 240) and is that there have been none. The Minister listens but will not discuss. The information is illuminating if expected. Dr. Dain and his colleagues must realize that they are dealing with a Minister who will stop at nothing to get his scheme through and in working order so that his name will be immortalized by people "going on Bevan" instead of "going on Lloyd George." Why must the Negotiating Committee always behave like the gentlemen they are instead of fighting the Minister with his own weapons? Why must they allow themselves to be gagged until the Bill is before Parliament? It is quite time that the general profession were given a strong lead and advised that in each area arrangements must be made forthwith to carry on practice *under our own control* in the event of an unacceptable Act of Parliament being thrust upon us.—I am, etc.,

Middlesbrough.

G. H. LOWE.

SIR,—Did the final paragraph in your excellent leading article entitled "The Minister Listens" convey a hint that in certain circumstances the medical profession might be advised to refuse service under the proposed new scheme of national health? If so, many of us who have abandoned hope may take heart again.

Unity in discussion and negotiation will apparently avail little or nothing, but in the last resort unity of action can prevail. A great and generous profession naturally shrinks from the idea of a "strike" which might imperil the health and lives of its fellow-men; equally so an educated and law-abiding profession would not presume to thwart or obstruct a lawfully elected Government. But to refuse a service which the profession with its special knowledge of humanity believes to be injurious alike to its own intellectual freedom and the public it serves would be neither illegal nor unconstitutional. Once the dotted line has been signed upon, however, further resistance will be illegal and useless. This is the last and only chance. Let us prepare for action before it is too late. Cultivated, free, and independent intellects must not be shackled in this land which has endured so much for freedom.

It is a sad sign of the times that even at this stage the writer prefers to sign

"NOT WITHOUT HOPE."

A Burning Topic

SIR,—It is not to be supposed that Dr. W. J. Gardner (Feb. 9, p. 220) intended his letter to be taken literally, any more, perhaps, than the correspondents he denounced did; but he is mistaken in his sweeping assertion that printing their letters can only cause irritation among your readers.

He is guilty, too, of a familiar form of false logic extensively used by correspondents in the lay press of demanding (in general terms) that A should be abolished in order to make room for B, when he has only a personal preference to offer as an argument, and A and B are not mutually exclusive. By all means let Dr. Gardner ventilate his complaint; but why must it be at the expense of harmless fellow-correspondents? A request for fair play should not itself reveal prejudice, and a letter demanding toleration should itself be tolerant. I do not seek to underestimate the difficulties of medical practice to-day; but I do not consider any reader of the *Journal* can consider himself starved of exhortation, controversy, or complaint. Is there to be no lighter touch, no relief, no diastole?

Five years or so of university life should make not only a doctor but also an educated man—perhaps even a cultured man. This aspect of the doctor's training is not easy to cultivate under present-day conditions; perhaps many of us have unduly neglected our small beginnings in this field; perhaps this generation, willy-nilly, cannot hope to attain the standards of culture and scholarship which graced the lives of many of our teachers and predecessors; but this does not justify brushing aside the work of others—unnecessarily and irrelevantly—as a mere irritation.

Personally, I am grateful to Lieut.-Col. Richards, Brig. Osmond, and Major Thomas for their erudition, so charmingly expressed; and to Major Thomas in particular for the savour

of his wit. It may be weak and foolish, but I fancy some of your readers, like myself, prefer to read Major Thomas writing of Priapus than Dr. Gardner writing of Dr. Gardner.—I am, etc.,

Lincoln.

ALLAN H. BRIGGS.

Myringotomy and Paracentesis

SIR,—The letter from my friend, Dr. J. K. Milligan (Jan. 19, p. 109), calls for some comment. He alludes to myringotomy as "cutting the drum." It should, of course, be the drum-head or membrane; the drum is a cavity, the tympanum. The membrane corresponds to the parchment cover of the ordinary musical drum.

Having "little Latin and less Greek" I have sought the help of my classical friend, Mr. J. F. Burns, in discussing the classical names. He tells me that "myringa," although it sounds like a Greek word, is unknown to Greek scholars, and the *Oxford Dictionary* says it is a modern Latin word. We may, I think, leave this point with the definition of "myringotomy" as "incising the tympanic membrane."

The name "paracentesis" presents more difficulties as it has acquired an additional meaning in later years. It is used for sucking out fluid from the chest and from the abdomen. Mr. Burns tells me that "spasma" is the word used by Aristotle for suction, but in medical Greek it is used for convulsion and therefore might be confusing if used in our desired meaning. The word "paracentesis" is firmly fixed in medical phraseology to-day. By analogy we can give it the additional meaning of sucking out when applied to an operation on the tympanum.

I conclude with an appeal that the word "paracentesis" should not be used as an alternative to "myringotomy," but should denote drawing off fluid from the tympanum.—I am, etc.,

Gulldford.

T. B. JOHNSON.

Medical Photography

SIR,—I would like to thank Mr. Maurice Lee (Sept. 22, 1945, p. 407) and Dr. S. Watson Smith (Oct. 20, p. 548) for their sympathetic reaction to my suggested scheme for an Institute of Medical Photography, and would ask others if it is in the interest of medical photography to condemn so hastily such a scheme as absurd and utopian. The value of some recognized training centre became obvious to me when, in charge of the photographic department of an important hospital, people often asked how and where they could be trained in medical photography. After extensive inquiries I could find no such place, and do not think the lectures and discussions given and arranged by scientific societies, valuable though they be, will train a photographer; also, many doctors have asked me where they could get such specialized work done for them. This seems to me an opportune moment in which to put forward such a scheme for consideration. If I did not make myself clear or put first things first I am sorry, and ask again if the medical profession and various societies will seriously consider such a scheme before the initiative slips into the hands of a commercial enterprise, or would they prefer it that way?

There are a number of people and books ready to tell us what any photographer knows: which camera and how to use it, the lights, the material, etc., but I have not yet found one person who can successfully demonstrate to me how best to photograph a lesion tucked away under the tongue in a sore and tender mouth—something entirely different from that required by a dental specialist—or how to take photographs, over a period of time which will be measurably comparable, of a patient in various stages of ill-health whose figure and lesion have both changed quite considerably in shape and size.—I am, etc.,

London, W.1.

HILDA ROBERTSON.

Memories of Clifford Allbutt

SIR,—In the summary of Sir Walter Langdon-Brown's paper on Sir Clifford Allbutt (Feb. 2, p. 174) a passing reference is made to the report that George Eliot took him as the prototype of Dr. Lydgate in *Middlemarch*. In one of the letters transcribed in *Cross's Life of George Eliot* she refers to her visit to Leeds (about 1875) when she was the guest of the Allbutts. She mentioned how greatly struck she was with the wide culture and charm of Clifford Allbutt. She was at the time working out

Middlemarch, and it is clear that the early career of Lydgate is closely paralleled by that of Allbutt. Both had studied in Paris—Allbutt under Trousseau, Lydgate under Broussais and Bichat, both had 'felt the growth of an intellectual passion' (*Middlemarch*, Chap. X) and had a special interest in fevers, and both had settled in a provincial town. Whenever the subject was mentioned Sir Clifford Allbutt preserved a Sphinx-like silence. Some forty years ago he had been invited to give away the prizes at the speech day of his old school—St Peter's York. The chairman, the dean, had asked me for particulars as to Allbutt's career in order to introduce him to his audience. I wrote *inter alia* that his first publications had been a series of articles on Greek medicine in the *Medico-Chirurgical Review*, and finished with the words 'He is supposed to be the prototype of George Eliot's Dr Lydgate in *Middlemarch*'. At the meeting the chairman forgot his cue and, producing my letter from his pocket, read its contents. I watched Allbutt's face carefully and noted that he made not the slightest sign of assent or dissent, nor was he approachable on the subject. Incidentally he once told me that he had attended only one confinement in his life. Dr Samuel Gee beat him in this by having attended three.

As one of those who listened to Allbutt's inaugural lecture at Cambridge in 1892 I can add my own personal testimony to that of Sir Walter Langdon Brown as to the lasting impression and intellectual awakening which it inspired in another of his audience—I am etc.,

G A AUDEN

Obituary

GEORGE W BRAY, M.B., CH.M., M.R.C.P.

Dr G W Bray, a leading specialist in the study and treatment of allergic disorders, died at his home in Hampstead on Feb. 12. He had been incapacitated by a severe illness last year, but it was hoped that this would not recur and that a further lease of active and fruitful work was in store for him.

George William Bray studied medicine at Sydney University, graduated M.B., Ch.M. in 1925, and then left to take up the post of Government medical officer at Nauru, an atoll in the Central Pacific which is a mandated territory administered by the Commonwealth of Australia. In 1926 he came to England and was appointed house physician and then resident medical officer at the East London Hospital for Children. His interest in allergic diseases in childhood was brought to the notice of the Hailey Stewart Trustees who nominated him asthma research scholar at the Hospital for Sick Children, Great Ormond Street. Much of the work done during his five year tenure of that scholarship was embodied in a monograph *Recent Advances in Allergy*, first published in 1931 with a foreword by Sir Arthur Hurst, who paid tribute to the author's flair for research combined with hard toil and clear thinking. The book went into a second edition in 1934 and a third in 1937, each of them carefully revised and brought up to date. Bray also wrote papers on hay fever and hay asthma and contributed the section on asthma to the *British Encyclopaedia of Medical Practice*, under the editorship of Sir Humphry Rolleston. By that time he had been appointed assistant physician to the Princess Elizabeth of York Hospital for Children and was engaged as clinical assistant to the asthma clinic at Guy's Hospital. Continuing his work in general paediatrics he was also appointed physician in charge of the children's department of the Prince of Wales's Hospital at Tottenham as well as physician for allergy there, and consulting allergist to the Children's Hospital at Hampstead. He had been admitted a member of the Royal College of Physicians in London in 1933 and was a member of the British Paediatric Association.

The articles by George Bray published in this *Journal* included a paper on 'The Hereditary Factor in Asthma and Other Allergies: the outcome of work done with a grant from the Asthma Research Council, an address on 'The Treatment of Allergic Diseases in General Practice,' read before the Leicester Medical Society, and an article on asthma written in 1935 for our series on Treatment in General Practice. We were

also indebted to him for a number of reviews of books on allergy and its clinical manifestations.

L. J. W. writes

Bray was one of the original members of the Asthma Research Club, which was formed when increased attention was devoted to asthma in this country from 1930 onwards. Largely as a result of the activities of the Asthma Research Council Bray had come from Australia, where he had worked in a different field. He was one of the first to recognize the importance of native foods in preventing avitaminosis in primitive peoples, in particular the native beer which was cloudy with yeast cells. He pointed out the harm which was done by would-be reformers in depriving children of this valuable food. He was, in fact, primarily a paediatrician, and his interest in allergy grew out of the problems he was faced with in treating bronchitis and papular urticaria in childhood. He developed in this country what might fairly be called the American approach to the subject—that is to say, the careful testing of allergens and the use of specific desensitization. It became rather a joke in the Asthma Research Club that one could always predict what would happen to an asthmatic if he went to an allergist or the specialists in the disease, and with Bray it was a full-scale and comprehensive range of skin tests. Hurst, who was the leader of the asthma research group, disliked the allergic hypothesis of asthma almost as much as the psychogenic and Bray had to struggle to get his aspect of the subject as much space as it deserved on the map. Nevertheless he succeeded. He had a wide knowledge of the allergic diseases and his book, *Recent Advances in Allergy*, was one of the best in a distinguished series of monographs. Coming from overseas with no advantages or connexion, he fought his way to a large London consulting practice by pure merit. He was a typical Australian in appearance and accent, vigorous, cheerful and unpretentious. He obviously found great happiness in his family and in the English countryside and coast. He was a lover of good cars, an unusually speedy driver in London traffic, and his staid and sardonic comments on the expert motorists he overtook on a journey home after a tiring clinic. One could usually count on meeting him at the luncheon room in the Royal Society of Medicine and his premature death has left a gap both in the and in the affections of a multitude of colleagues and patients.

R. C. WINGFIELD, M.B., F.R.C.P.

We regret to announce the death on Feb. 5 at Cambridge of Dr R. C. Wingfield, late medical superintendent of the Brompton Hospital Sanatorium at Frimley, whose long experience in the treatment of pulmonary tuberculosis in adults enabled him to write with authority several books and many papers and reports.

Rodolph Charles Wingfield, younger son of the Rev. Canon Charles Wingfield, of Welwyn, Herts, and Tiverton Castle, Devon, was born at Welwyn on Feb. 20, 1886 and after school days at Haileybury entered Trinity College, Oxford, as a student of medicine. He graduated B.A. and went on to St. Thomas's Hospital for his clinical course, qualifying as M.B., B.Ch. Oxon. in 1911. He then served in turn at St. Thomas's as house-physician, demonstrator of morbid anatomy, and assistant pathologist, won the Louis Jenner research scholarship, and was appointed medical officer in charge of the tuberculosis department. He took the M.R.C.P. in 1914 and was elected F.R.C.P. in 1928. The appointment to Frimley proved most congenial and he held it for a long period. His first book, *Modern Methods in Diagnosis and Treatment of Pulmonary Tuberculosis*, was written there and appeared in 1924, it was followed five years later by a *Textbook of Pulmonary Tuberculosis for Students*, a work valuable not only to medical practitioners but also to many people concerned in the prevention of tuberculosis which gave a sane estimate of what could and could not be done for sufferers from that disease and an appreciation of the true function of the sanatorium. Another and much smaller book by Wingfield, *Pulmonary Tuberculosis in Practice: A Modern Conception* (1937) contained teachings which should help to secure both early diagnosis and the correct handling of the vast number of people suffering from phthisis in its different clinical forms. This was in the author's words, 'an attempt to bridge the gap between the practitioner and the

specialist." The excellent reasoning and sound common sense were, however, marred by a complex and confusing terminology. It appealed more to tuberculosis officers and medical officers in sanatoria than to harassed general practitioners.

A memorial service was held on Feb. 10 in the Chapel of Brompton Hospital Sanatorium, where he had worked with inspiring energy and devotion for 25 years until failing health compelled him to resign his post in 1945. Wingfield's honesty and steadfastness and his administrative skill won the deep regard of colleagues and nursing staff at Frimley; they knew that the welfare of the patient as an individual came first in his thoughts and actions.

Dr. JOHN ALEXANDER HOWARD, who practised for many years at Beulah Hill, Upper Norwood, S.E., died on Dec. 27. He was one of the outstanding students of his time at Guy's Hospital, winning first-class honours in chemistry at the preliminary science examination at the University of London, first-class honours and medal in organic chemistry at the intermediate M.B., and first-class honours in medicine and in forensic medicine at the final examination. He also won an entrance scholarship in science at Guy's in 1889, and his essay on uraemia, which won him the Treasurer's Prize in 1893, was published in the *Guy's Hospital Gazette*. Dr. Howard took the English Conjoint diplomas and the M.B.Lond. in 1893 and the M.D. a year later, after serving as house-physician and obstetric resident at Guy's. He was surgeon to the Norwood Cottage Hospital for many years, and had been radiologist to the Croydon War Hospitals. He joined the British Medical Association fifty years ago.

Dr. THOMAS RICHARD WEBSTER ATKINS, surgeon on the s.s. *Cameronia*, one of the Anchor Line ships, died in Glasgow on Jan. 10 after a long illness at sea. He studied medicine in Edinburgh and Dublin and qualified L.R.C.P., L.R.C.S.Ed., and L.R.F.P.S.Glas. in 1898. He had seen active service in the South African War, and during the war of 1914-18 he was a captain in the R.A.M.C.(T.F.). He served for a long period in the trenches, and was wounded. After some years with the Cunard White Star Line Dr. Atkins joined the Anchor Line in 1938 and was with that company all through the war of 1939-45. He was on board when his ship was hit in December, 1942, and in the New Year's Honours List of 1944 he received the O.B.E. for his war work. He joined the British Medical Association in 1919.

Dr. WALTER GUYON RICHARDS, who died on Jan. 25, was chairman in 1922 of the Lewes and East Grinstead Division of the British Medical Association, which he had joined in 1902. Born at Winchester on July 10, 1869, son of Frederick William Richards, F.R.C.S., he was educated at Lancing, at Christ's College, Cambridge, and at St. Bartholomew's Hospital. He qualified in 1893 and took the Cambridge M.B. in 1897. For some considerable time he was an officer in the Indian Medical Service, and retired with the rank of major. During part of the war of 1914-18 he was in charge of the orthopaedic and electrical department of the Kitchener Hospital for Indian Troops at Brighton. He practised for some years in Holdenhurst Road, Bournemouth, and more recently made his home in Highgate.

We record with regret the death on Jan. 27 of Mr. JAMES WILMOT ADAMS, M.B., B.Ch., F.R.C.S., for many years a surgeon in the Colonial Service. Educated at Tonbridge School, he went on to Caius College, Cambridge, and to St. Bartholomew's Hospital and qualified in 1908, having obtained honours in the Natural Sciences Tripos of 1906. He joined the Colonial Service and worked first at Malacca, then at Penang, and finally at Singapore. He served his full time and then (before the late war) returned to this country and settled at Great Gransden, Bedfordshire. His health had been impaired by residence in the East, and he died very suddenly of coronary thrombosis. He married in 1913 Irene, youngest daughter of the late James Appleyard, M.D., J.P., of Longford, Tasmania, and had two children, who, with his wife, survive him. He will be remembered at his medical school as "Bill Adams," famous on the football field.

Dr. WALTER GEORGE MACDONALD, who gave notable service to many families by founding the Glasgow and West of Scotland Prisoners of War Relatives' Association in 1941, died on Jan. 28 at his home in Dalziel Drive, Glasgow. He had studied medicine at Glasgow University, and graduated M.A., M.B., Ch.B. in 1905. After holding the posts of house-physician and house-surgeon at the Victoria Infirmary, Glasgow, he was for a time honorary medical officer of the Penrith Cottage Hospital.

Dr. Macdonald served with a temporary commission in the R.A.M.C. throughout the 1914-18 war and was awarded the Military Cross. He joined the B.M.A. in 1908 and became a member of the Pathological Society. An enthusiastic card-player, he was the first president of the Scottish Bridge Union when it was founded in 1932.

Dr. ROBERT BALFOUR GRAHAM, who died at North Links, Leven, Fife, on Jan. 28, had a distinguished career and remained a member of the B.M.A. for 60 years, holding the post of secretary of the Section of State Medicine and Medical Jurisprudence at the Aberdeen Annual Meeting in 1914; he had also been president and hon. secretary of the Fife Branch. Born at Linthorne Manse in Roxburghshire on Aug. 25, 1859, son of the Rev. M. H. N. Graham, he entered the Medical School of Edinburgh University in 1880, qualified in 1884, obtained the F.R.C.S.Ed. diploma by examination in 1888, and the D.P.H. in 1894. Dr. Graham went to Leven 60 years ago; he was appointed M.O.H. for the borough in 1904, and examiner in public health for the Royal College of Surgeons of Edinburgh in 1911. He was an active worker in the St. John Ambulance Association from the year 1890 when he began as an examiner, and was later appointed lecturer and honorary life member. In the war of 1914-18 he served as senior medical officer at a Command Depot with the rank of lieutenant-col., R.A.M.C.(T.), and had also been county director of the Scottish Territorial Red Cross Brigade. Keenly interested in ex-Service men's affairs he was president of the Leven Branch of the British Legion and also of the Fife and Kinross Area Council, and for some time vice-president of the National Executive of the British Legion in Scotland. He received the M.B.E. and the Volunteer Decoration, and was a J.P. for Fifeshire and a past-president of the Fife Medical Association.

Dr. FRANCES E. TURLE SAINT (*née* Turle Evans), who died in retirement at Herne Bay on Jan. 30, came of a family who had been doctors for four generations. She was the youngest daughter of Dr. Evan Evans, R.N., and was born in the City of London in 1867. She was educated at the Maria Grey School, the London School of Medicine for Women, and the Royal Free Hospital, whence she qualified L.R.C.P.&S.Ed., L.R.F.P.S.G. in 1897. As Dr. Turle Evans she was particularly interested in obstetrics and worked at the Clapham Maternity Hospital (now the Annie McCall Hospital) and its Battersea Branch until 1901, when she started private practice in Harlesden, London, N.W. There she worked hard and very successfully until her marriage in 1908 to the Rev. F. Guy Saint, Rector of Wapping, and late Rector of Great Tey, Essex. She did no regular medical work there, but continued to be an examiner for the Central Midwives Board, and in a quiet way was of immense medical help in both the town and country parishes. In 1932, on the death of her husband, Dr. Turle Saint retired to Herne Bay, and even there she continued to help and advise a young newly qualified nephew—of the fifth generation. Her death is mourned by a very large circle of friends and patients.

Dr. ARTHUR CECIL HOVENDEN of East Sheen, S.W., who died on Jan. 31, aged 76, was one of the best-known figures in the Sheen area. He was a Guy's student, and soon after taking the Conjoint diplomas graduated M.B., B.S.Lond., with honours in medicine, in 1894; six years later, after acting for a time as clinical assistant at Great Ormond Street Hospital for Children, he began to practise in partnership at Sheen, becoming senior partner in 1912. Dr. Hovenden joined the British Medical Association in 1904. In his younger days one of his greatest pleasures was a canter or a gallop in Richmond Park before breakfast. His other interest, apart from medicine, was model engineering and the study of railway literature, and he was a member of the Stephenson Locomotive Society.

The death of OGLE WOODS at the age of 70 brings to a close a long and gallant struggle against a severe and crippling disability. While a student at St. Thomas's Hospital he contracted a tuberculous kidney, for which a nephrectomy was performed. After doing various hospital appointments Woods settled in general practice at Bridgend, but some years later he was compelled to abandon this as tuberculosis of the knee developed eventually necessitating an amputation. No longer capable of coping with his extensive general practice he turned to surgery and with that end in view accepted the post of R.S.O. at Swansea General Hospital during the years of the first world war; in due course he secured his F.R.C.S.Ed. and subsequently received the appointments of supernumerary surgeon and also orthopaedic surgeon at that hospital, later to become a full surgeon. Woods possessed a lovable disposition with outstanding honesty of purpose, sound common sense, and great courage in surmounting his physical infirmities. These did not impa

his keen sense of humour, and often his colleagues would enjoy the sound of his laughter in the intervals of work in the theatre. He took an active part in hospital politics and was fearless and downright in expressing his views in the board room. His doggedness was mitigated by his eminent fair mindedness, and was valued and liked even by his most persistent opponents. By his death his hospital has lost an outstandingly valuable counsellor. Woods did not allow his infirmities to deprive him of one open air pastime, as a fisherman he excelled, being an expert entomologist making his own flies and learned in the ways of trout. In spite of his artificial leg he would overcome the difficulties and rough conditions of Welsh trout streams during his scanty leisure. Recent times added to his professional labours but in spite of advancing years, pain and disablement his undaunted spirit carried him on perhaps to shorten his days though that would never deter him. Swansea has lost a very notable man. He will not be forgotten.

H W G

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on Feb. 12 the name of R. H. S. Thompson, D.M., Fellow of University College, duly nominated by the Board of the Faculty of Medicine as Dean of the Medical School from Feb. 1 to Oct. 1, 1946 (vice K. J. Franklin, D.M., F.R.C.P., Fellow of Oriel College, resigned) was submitted to the House and approved.

UNIVERSITY OF CAMBRIDGE

Postgraduate Courses for Ex-Service Medical Officers

It is proposed to hold 14-day refresher courses in general medicine for medical officers released from H.M. Forces at the South-end-on-Sea General Hospital commencing April 1 and at Addenbrooke's Hospital Cambridge in July. There will also be a 14-day course in social and industrial medicine at Luton in May. Assistance will be given in procuring accommodation for the South-end course on application to the secretary, South-end-on-Sea General Hospital. General practitioners may attend these courses should vacancies occur. Further particulars and forms of entry may be obtained from Dr. Firth, Trinity Hall, Cambridge.

At a Congregation held on Feb. 9 the following medical degrees were conferred:

M.D.—A. C. Cunliffe, J. W. Lawe, M.B. B.Chir.—F. T. J. Hobday, *M. W. P. Ward, *P. K. Ledger, *J. H. Gough, *J. O. P. Edwards, *J. B. Metcalfe, *P. H. Hewitt, J. E. Blundell, A. C. Elithorn, M.B.—C. M. Heath.

* By proxy.

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE

The Professor of Anatomy, Mr. J. Z. Young, F.R.S., will give his inaugural lecture on Thursday, Feb. 28 at 5.15 p.m., in the Anatomy Lecture Theatre, with the Provost in the chair. Subject: "Patterns of Substance and Activity in the Nervous System."

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council, held on Feb. 8, Charles Herbert Stuart-Harris, M.D., F.R.C.P., late colonel, A.M.S., was appointed to the full time Chair of Medicine in the University.

The Council received the resignations of Prof. Wilson Smith (professor of bacteriology), Dr. Robert Platt (lecturer in medicine, on his appointment to the Chair of Medicine in the University of Manchester), Mr. W. J. W. Sharrard (temporary demonstrator in anatomy), and Prof. A. E. Barnes (of his academic duties), and thanked them for their services to the University.

UNIVERSITY OF EDINBURGH

In 1944 Sir Robert McVittie Grant made a gift to the University of Edinburgh for the foundation of a professorship of dermatology, and the University Court has now appointed Dr. G. H. Percival to this chair, which is named after the donor. The Edinburgh Medical School was a pioneer in this country in providing systematic teaching in diseases of the skin, and the new professorship is the only one of its kind established so far in Britain. The skin department of the Edinburgh Royal Infirmary was opened in 1894 and was replaced by new and much larger premises in 1936. Beyond this accommodation the municipal authorities of the city have paid much attention to the provision of beds and the organization of treatment for dermatological cases. Dr. Percival graduated in medicine in 1923, and in 1931 proceeded M.D. and was elected F.R.C.P.E.; five years later he was appointed a physician to the skin department

of the Royal Infirmary. He has been responsible for the later editions of Sir Norman Walker's *Introduction to Dermatology*.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council held on Feb. 14 with Sir Alfred Webb Johnson, President, in the chair, D. E. Ashworth, Underwood, was appointed Thomas Vicary, Lecturer for 1946.

The Hallett Prize was awarded to Mr. Ramchand Nigam of the University of Lucknow.

Sir Henric Ogilvie and Mr. L. E. C. Norbury were reappointed as representative members of the Council on the Imperial Cancer Research Fund and Mr. Eardley Holland was re-elected as the representative of the College on the Central Inquiries Board.

Mr. Hedley White, Mr. J. B. Oldham, Mr. M. F. Nicholl, and Mr. Harold C. Edwards were re-elected members and Mr. Julian Taylor was elected a member of the Court of Examiners.

Diplomas of Membership and Diplomas in Public Health were granted jointly with the Royal College of Physicians of London to the candidates whose names were published in the report of the meeting of the Royal College of Physicians of London in the *Journal of Feb. 16* (p. 260).

The main library of the College was not seriously damaged when other parts of the building were bombed, and the books have now been returned to the shelves. Several tons of books had been evacuated to Downton Castle, Ludlow, Shropshire, Worcester, and the National Library of Wales. Rearrangement of the library is now proceeding and the Reading Room is open once more to students from all parts of the world.

Professional lectures on applied physiology and pathology will be given on Mondays, Wednesdays and Thursdays throughout March (Friday, March 8 in place of Thursday, March 7). The lectures on pathology will be given by Prof. R. A. Willis. The lectures on applied physiology include Profs. R. J. S. McDowall, Samson Wright, B. A. McSwaney, F. R. Wilson, O. G. Edholm, H. P. Gilding and W. R. Spurrell. Further particulars will be issued later.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

The trustees of the Dr. James Watson Prize Fund invite applications from Fellows of the Royal Faculty to give the James Watson lecture for the year 1946-7. The subject is unrestricted but should deal with an aspect of medicine or surgery to which the lecturer has devoted special study. The lecturer's name must have been on the *Medical Register* for a period not exceeding 15 years, value of lectureship £30. Applications, indicating the proposed subject, should be made in writing to the Secretary of the Royal Faculty, 242, St. Vincent Street, Glasgow, by March 15.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly business meeting of the President and Fellows of the Royal College of Physicians of Ireland, held on Feb. 1, M. L. Abrahamson, J. B. Ryder, and F. S. Stewart were admitted Licentates and Members of the College.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council, held in the College House on Jan. 26, with the President, Mr. Eardley Holland, in the chair, the following candidates were elected to the Membership of the College: Constance L. Bynnon, E. W. C. Buckell, W. Calvert, R. G. Cross, S. N. Gardé, Perla Greeves, Emilie E. Guthmann, W. P. Hirsch, W. Kearney, A. H. C. Walker, Margaret Weddell, May D. Weserman.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S. Glas.

J. B. Bate, G. Brill, J. E. B. Dodd, E. B. Cowan, R. M. Dykes, A. F. M. El-Norany, G. W. Farrington, J. L. Fice, Janet H. A. Finlay, A. Foreman, Hanna M. M. Gupta, W. Henderson, Mary P. Hughes, F. J. G. Kissella, A. K. Kutschewka, Muriel M. Macfarlane, E. MacSwaney, Almena M. Marab, T. A. Morton, R. A. A. Ross, E. D. S. Sar, J. S. P. Wilson.

L. Seewald, a graduate of a recognized foreign university, was also admitted a licentiate.

The Services

The President of the U.S.A. has bestowed the Legion of Merit, Degree of Commander, on Surg. Rear Admiral C. P. G. Wakeley, C.B., for distinguished services to the United States Medical Service.

Surg. Lieut. D. R. Rigg, R.N.V.R., has been awarded the Czechoslovak Military Medal of Merit, First Class, for service to the Czechoslovak Section of Warship Hospital.

Medical Notes in Parliament

Leprosy in India

Asked on Jan. 28 whether he could give any statistics of the prevalence of leprosy in India Mr. ARTHUR HENDERSON replied that the figure given in the 1931 census (the last in which such a figure was included) was 150,000. Local surveys suggested that the real total of cases was about one million, of which only about one-quarter were at any one time infectious, some being very slight cases indeed. Existing data gave no reliable indication whether the disease was increasing or decreasing.

Venereal Disease in B.A.O.R.

Replying on Jan. 29 to Sir Waldron Smithers, Mr. LAWSON observed that it was difficult to estimate to what extent the present level of venereal disease in the B.A.O.R. was attributable to the removal of the ban on fraternization. All those concerned were fully aware of the importance of reducing the incidence of venereal disease to the minimum. All practicable steps towards this end had been and were being taken by the Army medical services.

Malaria Research Institute in Africa

On Jan. 30 Mr. CREECH JONES informed Sqdn. Ldr. Donner that a considerable amount of control and research work on various aspects of the malaria problem had been and was being done in both East and West Africa, but there was no specific institute on the lines of the Malaria Institute of India. The establishment of such an institute was one aspect of the whole problem of the future organization of medical research for the Colonies. It was being considered by the Colonial Medical Research Committee, which was set up last year under the chairmanship of Sir Edward Mellanby by the Secretary for the Colonies and the Medical Research Council.

Medical Specialists in the Services

Air Cdre. HARVEY inquired on Feb. 5 what steps were being taken to provide specialists for the medical services of the Navy, Army, and R.A.F. to replace Service specialists retained beyond their release groups.

Mr. KEY said efforts were being made through the Central Medical War Committee to recruit practitioners up to the age of 40 who were qualified to serve as specialists in the Forces. The number remaining available in the E.M.S. and civil practice was much more limited than was commonly supposed, but the committee, in consultation with its local committees, was constantly reviewing the staffs of hospitals to decide which men could be spared or replaced. Mr. KEY added that Mr. Bevan had communicated with hospitals concerning the use of demobilized officers for such replacements. Short-service commissions for 18 months were being offered to both practitioners so recruited and specialists over the age of 40 who volunteered. The Medical Personnel (Priority) Committee had decided that it would be unprofitable to reopen the cases of specialists who in the past had been found medically unfit.

Aliens in the R.A.M.C.

Mr. LAWSON on Feb. 5 told Col. Harry Morris that the War Office had accepted upwards of 500 non-British doctors for service as medical officers in the R.A.M.C. during the war. The end of the war and the rapid run down in all theatres resulted in a reduction of the number of posts in which these practitioners could suitably be employed. In consequence no further appointments were being made, except in the case of those in the specialist category. Non-British practitioners already serving who had been recommended were, however, permitted to extend their service until general demobilization or for so long as their services were required.

Release of Doctors from R.A.F.

In answer on Feb. 6 to Air Cdre. Harvey, Mr. JOHN STRACHEY announced that medical officers in the R.A.F. in Group 27 would be released in February. General duty medical officers in the Army were being released up to Group 38 by the end of February, and their colleagues in the Naval medical services were being released up to Group 40. These releases all resulted from a Government decision that there should be two medical officers per 1,000 men in each of the three Services. The release of R.A.F. medical officers was at present up to the general average for the R.A.F. The Air Ministry could not go faster than this because the wartime proportion of medical officers in the Air Force had been much lower than in the Army

or the Navy. He hoped for a further intake of doctors for the R.A.F. this year so that the present disparities in release could be reduced.

Nutrition in Newfoundland

The report on nutrition in Newfoundland made by a committee of experts from the United Kingdom, Canada, and the United States in 1944 and published in 1945 has been the subject of detailed study by the Newfoundland Commission of Government. A further report is expected shortly from Dr. Cuthbertson, now director of the Rowett Research Institute, who visited the island last August. The Newfoundland Government has taken steps, including the fortifying of flour and margarine, to overcome the lack of balance in the normal diet of sections of the Newfoundland people.

Atomic Energy

Mr. ATTLEE on Feb. 6 told Mr. Blackburn that little progress had as yet been made in the development of atomic energy for peacetime purposes. He hoped that the co-operation which had existed between this country and the United States in this field during the war would be continued in the future.

Treatment for Homosexuality

Mr. EDE does not think that progress will be facilitated by the appointment at the present stage of a committee to examine the use of curative or psychological treatment of persons guilty of homosexual offences. Not all persons sentenced to imprisonment for these offences are suitable subjects for psychological treatment. He agreed that the treatment should be available in all cases where there is a reasonable prospect that it will have beneficial results.

Paper for Textbooks

Mr. BEVAN said on Feb. 7 that there was difficulty in obtaining midwifery as well as other textbooks owing to the shortage of paper and printing labour. He had discussed the matter with the President of the Board of Trade, who had arranged for considerably increased supplies of paper to be made available to publishers, and for 750 printing operatives to be released from the Forces under Class B in order to ease the labour shortage.

World Food Shortage: Britain's Share

The world food shortage was debated by the House of Commons on Feb. 14. Sir BEN SMITH said the situation had been completely changed by the exceptionally heavy demand arising from the liberation of Europe, coinciding with adverse weather and poor crops in many areas of the world. Against world import requirements of more than 17,000,000 tons of wheat in the first six months of 1946, less than 12,000,000 tons would be available. Many millions of people in Europe and the Far East would face starvation. In Europe 125,000,000 people would have to subsist on less than 2,000 calories a day. In some areas large numbers would receive as little as 1,000 calories a day. There were many possibilities of further deterioration. This country might have to raise the wheat extraction rate still higher or use coarse grains as diluents in bread. He hoped it would be possible to avoid that. In rice the quantity available for export from all sources during 1946 was, at most, 3,000,000 tons, whereas the world requirements were 6,000,000 tons. Britain would not get more than 300,000 tons of ground nuts, against 600,000 tons allocated by the Combined Food Board. That represented 130,000 tons less oil. Of whale oil Britain was unlikely to get more than 100,000 tons, against 135,000 tons expected. The world sugar position was precarious, and world requirements were increasing. It was not now possible to increase the bacon ration. Cheese and starch caused him anxiety. There were favourable prospects for fruit. Oranges, lemons, and grapefruit had been made available in increasing quantities. He intended to augment British supplies of vegetables and fruit by imports. There were more shell eggs, and he had never intended to discontinue the issue of dried egg permanently. Milk supplies were better this winter than last.

In replying to the debate Mr. DALTON indicated that he did not propose to reduce the imports of tobacco or films from America.

Release Leave in Cases of Venereal Disease.—In reply on Jan. 29 to Mr. Walker, Mr. LAWSON said that men were not allowed to go home on release leave while suffering from venereal disease in a communicable form. In cases where a man had received sufficient treatment in the Army to render the disease non-communicable he was allowed to go on release leave. He was provided with a card which showed the treatment he had had and contained the address of the nearest civilian treatment centre to which he should report for advice, treatment, or observation. He was also encouraged to notify the medical officer of health of his home district of the fact that he had been furnished with such a card.

Osteopaths in a National Health Service—Mr J. L. WILLIAMS inquired on Jan 25 what would be the position of non-registered practitioners of osteopathy, in regard to practice, under the new National Health Service. Mr BEVAN said he thought he ought not to anticipate the proposals for the new service as a whole, which he hoped before long to submit to the House.

Service Patients waiting Admission to Sanatoria—Mr LAWSON told Major Leese Bourke on Jan 29 that the number of military patients in the United Kingdom waiting admission to civil sanatoria was 796. The average waiting period was 7 to 8 weeks. While waiting these patients were retained in military or E.M.S. hospitals, where they were given suitable treatment. This matter was already under consideration as a matter of urgency with the Minister of Health.

Grants for Medical Training—Miss WILKINSON stated on Jan 31 that up to Jan 24 under the Further Education and Training Scheme, 130 awards had been made for training in medicine. The grants provided for maintenance and the cost of fees. All applications from men and women who appeared to be eligible under the scheme would be very sympathetically considered.

Training Nurses for the Colonies—Mr GEORGE HALL has commended to the consideration of Colonial Governments those recommendations of the report of the Committee on the Training of Nurses for the Colonies which relate to the development of the nursing and midwifery services in their territories and the local training of staff for those services. He has asked for reports to be furnished towards the end of this year on the progress made. He has accepted the recommendation that a nurse adviser should be appointed to the staff of the Colonial Office.

Notes in Brief

Mr Bevan told Sir Henry Morris-Jones on Jan 22 that there had been some complaints about the relative insolubility of some samples of British penicillin, but there had also been complaints about some American penicillin. Supplies of British penicillin had now greatly improved in quality and in some cases were being asked for in preference to American.

Mr John HIND stated on Jan 24 that permission had not been withheld for the dispatch to the British zone in Germany of a complete mobile hospital unit organized by the Paderewski Memorial Hospital in Edinburgh. Unfortunately the organizers of the unit were unable to find the Polish staff necessary for its operation. The equipment was being assembled by UNRRA for use in Poland.

There is no restriction on the supply of penicillin to the Colonies. Their full requirements can now be ordered through the usual channels.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* acute pneumonia, measles, diphtheria and dysentery were more prevalent, the increases were, respectively, 344, 260, 68, and 49. The only diseases with a lower incidence were scarlet fever with 69 fewer cases, and whooping-cough 64.

The number of cases of acute pneumonia increased throughout the country, the only exception being Lancashire, where the notifications decreased by 49. Large increases in measles affected two areas—Suffolk 117, and London 121; 40% of the total notifications of measles were recorded in these two counties. The largest increases in diphtheria were Lancashire 23, Yorks West Riding 13, and London 11. The notifications of whooping-cough declined for the first time this year; the largest of the local fluctuations were an increase in London of 48, and decreases in Lancashire of 28, and Middlesex 20.

Dysentery notifications were the largest since last June. A further 130 cases were reported from the outbreak in Leicestershire. The other large centres of infection were Yorks West Riding 45 (Wharfedale R.D. 16, Leeds C.B. 10), Lancashire 44, Warwickshire 29 (Birmingham C.B. 26), Northamptonshire 15, London 13, Surrey 13, Northumberland 10.

In *Scotland* rises were recorded in acute primary pneumonia 41, and scarlet fever 15, and falls in measles 23, and diphtheria 19. The notifications of diphtheria (108) are only 63% of the number at the beginning of January, giving the lowest total since mid-August.

In *Ireland* the notifications of diphtheria, after falling slowly for a month, rose from 53 to 75. The cases are widespread and involve forty-one areas. In Dublin C.B. increases were recorded for whooping-cough 16, measles 8, and diarrhoea and enteritis 5.

Week Ending February 9

The notifications of infectious diseases in *England and Wales* during the week included* scarlet fever 1 405, whooping-cough 1 253, diphtheria 477, measles 1 211, acute pneumonia 1 832, cerebrospinal fever 98, poliomyelitis 11, dysentery 337, typhoid 6, paratyphoid 8. Deaths from influenza in the great towns numbered 304.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb 2

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for— (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland

Figures of Births and Deaths, and of Infant Mortality, are given for— (a) The 126 great towns (b) The 13 principal towns in Eire (c) The 13 principal towns in Northern Ireland

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available

Disease	1946					1945 (Corresponding Week)

Stillbirths Rate per 1,000 total births (including stillborn)	214	28	32	—	—	199	14	32	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county) and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

Medical News

Members of the B.M.A. are reminded that the Association possesses a small collection of volumes presented to it by the Worcester Medical Society and named after the founder of the Association, Sir Charles Hastings. It is of historical interest and has recently been catalogued. It may be seen by any member on application to the librarian.

At the meeting of the Royal Statistical Society on Wednesday next, Feb. 27, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., Prof. Major Greenwood, F.R.S., will read his paper on "The Statistical Study of Infectious Diseases."

At a meeting of the Medico-Legal Society to be held at Manson House, 26, Portland Place, W., on Thursday, Feb. 28, at 8.15 p.m., Dr. Letitia Fairfield will read a paper on "The Supernatural in the Law Courts, with Special Reference to the Witchcraft Act, 1735." Members may introduce guests to the meeting.

At a meeting of the Association of Austrian Doctors in Great Britain to be held on Feb. 28 at 7.30 p.m., at 69, Greencroft Gardens, N.W.3 (near Finchley Road Station), Lieut.-Col. James Marshall will speak on modern treatment of venereal diseases. Guests will be welcome.

A whole-day conference of the Nutrition Society will be held at the London School of Hygiene and Tropical Medicine (Keppel Street, W.C.) on Saturday, March 2, beginning at 11 a.m. The general subject for discussion is "Nutrition in Colonial Territories" and the following papers are to be communicated: Dr. B. S. Platt, The Problem and Principles Underlying its Solution, followed by Ministry of Information film "To-day and To-morrow"; Dr. H. S. Stannus, Malnutrition in Colonial Territories; Dr. N. C. Wright, Relation of Animal Husbandry to Human Nutritional Needs; and Dr. Audrey I. Richards, Sociological Factors. The discussion will be opened by Mr. A. J. Wakefield and Prof. R. Firth. Non-members are only admitted to meetings of the society by the introduction of a member, the meetings are private, and no unauthorized account may appear in the press. Further details of the society may be obtained from the honorary secretary, Dr. Leslie J. Harris, Nutritional Laboratory, Milton Road, Cambridge.

The annual dinner and general meeting of the London Irish Medical Golfing Society will take place on Thursday, March 7, at the Charing Cross Hotel, Strand, W.C.

The annual general meeting of the Society of Public Analysts and Other Analytical Chemists is to be held at 5.15 p.m. on Friday, March 8, at the Chemical Society's Rooms, Burlington House, Piccadilly, W. Immediately after the transaction of business Dr. J. H. Quastel, F.R.S., will give a lecture on "Biochemistry of Soil." The Council would welcome the presence of members' wives and friends at the address, which will begin about 6 p.m.

The Ministry of Health announces that a demonstration by ex-Service physical training instructors will be given on Friday, March 8, in the rehabilitation department of the Pinderfields Emergency Hospital, Wakefield. It is to be watched by the Lord-Privy Seal (Mr. Arthur Greenwood) and representatives of Government Departments, local authorities, and hospitals. The instructors who are giving this demonstration are undergoing a six-months course organized by the Ministries of Health and Labour. During the war a number of physical training instructors from the Services were attached to emergency hospitals to help in the rehabilitation of patients. Their work was so successful that the Ministry of Health is anxious to retain their services now that they are being released from the Forces. About 150 of these instructors have been selected for this special course, in order to qualify them as remedial gymnasts. They will then be available for posts in hospital rehabilitation departments, special rehabilitation centres, industrial health centres, etc.

The January/February number of *Industrial Welfare and Personnel Management*, published by the Industrial Welfare Society, 14, Hobart Place, Westminster, S.W.1, includes an article by Dr. T. M. Ling describing the work of Roffey Park Rehabilitation Centre, where indeterminate cases of ill-health arising from industry are treated; also a note by Dr. G. H. Gange, giving particulars of the annual cost of the medical department of the Glacier Metal Co., Ltd.

The following members of the honorary medical staff of the National Hospital, Queen Square, who were on active service, have now taken up their duties again: Brig. G. Riddoch, Air Vice-Marshal Sir C. P. Symonds, Surg. Capt. Macdonald Critchley, and Air Cdre. D. Brinton.

In the Cathcart Division of Glasgow by-election Mr. J. Henderson (Cons.) was returned with 13,696 votes; Mr. A. B. Mackay (Soc.) polled 9,689; and Dr. W. O. G. Taylor (Scottish Nationalist) 2,700.

Dr. Frederick Dillon has been appointed physician to the Department of Psychological Medicine at University College Hospital.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent*, London. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Inheritance of Retinitis Pigmentosa

Q.—A woman of 26 was found to have retinitis pigmentosa about four years ago. There is no history of the condition having been present in any of her forbears. The fundus shows the changes typical of the condition, though the vessels are, as yet, little affected. While she has been under observation the peripheral field had progressively shrunk until now it is down to about 20 to 30° all round, with an isolated patch of vision temporarily in each eye. (1) If she marries and has children what are their chances of being similarly affected? (2) How long is she likely to retain sufficient vision to continue the practice of her profession?

A.—From the genetic point of view this patient is exactly comparable with the one mentioned in "Any Questions?" in the *Journal* of Nov. 24, 1945 (p. 752). Dominant inheritance is rare and is ruled out because the disease was not present in her forbears. Sex-linked inheritance is also rare and is ruled out by her sex. Apart from the possibility mentioned below this patient doubtless owes her condition, as do the great majority of sufferers, from retinitis pigmentosa, to a recessive gene. Unless she proposes to marry a blood relative the chance that her husband will be a carrier is remote, and only if he is a carrier can affected offspring appear. Thus the odds against any child being affected are some hundreds to one, and there is no genetic reason why she should not marry and have children. It is true that her children would be carriers and that in some future generation the abnormal gene might again meet its like. But this is no reason for refraining from marriage. In all probability most of us carry at least one such undesirable recessive, the only difference being that she knows it and we do not. The question does not state whether any brothers or sisters are affected. If not it is possible that the case is sporadic and may not be hereditary at all. This possibility strengthens the already very strong case for marriage and children if she desires them.

The ophthalmological prognosis is a much more difficult question. The disease is very variable in its course. Good features in this instance are the normality of the retinal vessels and the absence, presumably, of atrophy of the disks. The recent shrinking of the fields is, of course, an unfavourable indication. Retinitis pigmentosa is not necessarily a relentlessly progressive disease; it may become relatively stationary at any time. And it need not end in blindness; many sufferers retain a useful amount of vision through a long life. This patient should be advised to carry on and hope for the best.

Causation of Facial Tic

Q.—An educated young woman of about 30 had schizophrenia three years ago, cured by drug treatment. For the last two years she has been well, but a facial tic, which she has had since childhood, appears to have become worse, especially when she is in company or excited, or when absorbed in reading or in listening to music. At such times her mouth twitches violently, and in a way that is disfiguring. Would it be safe to speak to her about this, with the suggestion that she should try to control it. Might drawing attention to this defect have untoward effects? If so, is any other line of action indicated?

A.—Although this is obviously not a mere reflex spasm, it is often found that there is some slight local irritation—e.g., an unerupted molar, or chronic middle-ear discomfort—so that when the patient is emotionally "worked up," as in the instances given, the energy tends to discharge itself in the focus of irritation, and that in an exaggerated manner. This tic, however, may be a neurosis from childhood, which may be precipitated by emotional problems; a talk with her about any present-day worries might help. The most common psychological cause is a frustrated or suppressed assertiveness. But these problems may be of too deep a nature to discover except by analysis. In either case we can see no harm in mentioning the matter to her in a matter-of-fact way. If the first explanation

is correct it may help her to control and "canalize" her energy for proper use. If the second, it would be an introduction to a discussion of the possible worries underlying it. But perhaps the simplest, and possibly correct, diagnosis is that she had a previous slight displacement of a vertebra from a fall (which sometimes even an x-ray investigation cannot detect), and that this was accentuated by the drug treatment, especially if that were of the convulsive type. A manipulative surgeon might put it right.

Diagnosis of Syphilitic Kidney

Q.—An elderly male patient with gross oedema, impaired renal function, and a positive W.R. and Kahn, admits to no previous disease. How can one differentiate between a second-stage nephritis (or a nephrosis) and a "syphilitic kidney"? What are the treatment and the pathology of the latter?

A.—Syphilis of the kidney is rare, and impaired renal function coupled with a positive W.R. and Kahn does not necessarily indicate a syphilitic nephritis. The best method of differentiating a second-stage nephritis from a syphilitic kidney is the therapeutic test. A syphilitic nephritis should be treated with neosarsphenamine, in small doses at first, increased later. Bismuth may be employed as well, but with care. It is possible that penicillin might be effective, but no record of its use in such a case is known. Syphilitic nephritis may be early or late and may be classified as follows: *Early*—(1) acute glomerular, showing little albumin and numerous red blood cells in the urine; (2) acute tubular, the urine containing very large amounts of albumin with granular, hyaline, and fatty casts. *Late*—(1) chronic glomerular nephritis; (2) chronic interstitial nephritis—both these with a small contracted kidney; (3) chronic parenchymatous nephritis, with a large pale kidney. It cannot be stressed too strongly that a positive W.R. and Kahn do not necessarily indicate the presence of syphilis, particularly in the Tropics.

Penicillin in Bronchiectasis

Q.—Is penicillin of any value in the treatment of old bronchiectasis in a patient unsuitable for operation?

A.—The sputum produced by the type of case mentioned usually contains a very varied flora, including *H. influenzae* and *F. fusiformis* as well as *Str. viridans*, non-haemolytic streptococci, and pneumococci. Many of these organisms will be found to be penicillin-sensitive, but a concentration up to 2 units per ml., will usually be necessary to inhibit all of them. The concentration in the sputum after the intramuscular injection of penicillin never reaches the necessary level, and therefore is of little use. Local treatment must necessarily be undertaken and is most conveniently given by an inhaler. A solution of penicillin of 10,000 units per ml. is used and the patient inhales during the day for five minutes each hour. The length of time of inhalation should be increased until the sputum contains a concentration of about 5 units per ml. of penicillin; it may then be sterile. Alternatively, penicillin solution, 10,000 units per ml., may be injected into the trachea by the same technique as for a bronchogram; 5 ml. of solution should be used each day for ten days.

Irradiated Blood

Q.—Has any work been done on the irradiation of transfusion blood in the treatment of rheumatism and allied conditions?

A.—Irradiated blood has been used for a great variety of diseases, including arthritis. The usual procedure is to expose the citrated blood to ultra-violet irradiation; special apparatus has been devised for the purpose. It is probably little more than an elaborate form of protein shock. The literature is summarized in *The Blood Bank and the Technique and Therapeutics of Transfusions*, by R. A. Kilduffe and M. de Bakey (London, 1942, pp. 133, 134).

Rh Antigens

Q.—In an article on irregular haemagglutinins after transfusion, Callender and Paykoç (Jan. 26, p. 119) mention the six Rh antigens included in Fisher's scheme. What is this scheme, how many Rh antigens are now recognized, and what are they? What is the significance of the letters CDe, cDe, and cde used after Rh₁, Rh₂, and rh, respectively?

A.—When Fisher's theory was proposed in 1944 it provided rhyme and reason for the rather bewildering Rh antigen-antibody reactions then known. It also made certain predictions which are gradually being verified. According to this theory three adjacent genes are responsible for the Rh blood-group antigens, not one gene as had been previously supposed. Each of these genes has at least two alternative forms, called C or c, D or d, and E or e. Each chromosome must carry three genes, which may be CDE or CDe or cDE, etc. As an individual has two of each of the 24 different human chromosomes he will have two of the Rh chromosomes, and each may carry any combination of the three alternative pairs. For example, a person may have received CDe from one parent and cde from the other. This particular combination—CDe/cde—is common in Britain and the U.S.A. The six Rh genes produce six

corresponding antigens on the red cell, each capable of inducing a corresponding antibody. (This must be qualified by saying that d at present represents only the absence of D. A year ago e denoted only the absence of E, but the discovery of an anti-e serum, predicated some time before by Fisher, makes it possible to recognize e as an antigen.) Not counting d, there are six Rh antigens—D, C, c, E, e, and C* (C* is a third alternative to C or c, only recently discovered)—which can be identified by positive tests. There is every reason to suppose that d will eventually become recognizable as a positive character.

Rh₁ is the original name of the "gene" which, according to Fisher, actually consists of a short strip of chromosome involving three genes—C, D, and e. Similarly Rh₂=cDE; rh=cde; Rh₃=cDe; Rh₄=Cde; Rh₅=cde; Rh₆=CDE; and Rh₇=CDe (Rh₇ has not yet been isolated). These earlier names are often convenient—for example, the genotype CDe/cDE is usually called Rh₁Rh₂, or R.R₂. The combinations involving C* have not been given Rh names. Successful detailed predication, such as that achieved by Fisher, must be rare in biology. A letter about the theory appeared in *Nature* for Jan. 12, 1946 (p. 43).

Blood Urea and Blood Uric Acid

Q.—Is the blood uric acid raised in azotaemic nephritis? To what extent is the blood urea increased in cases of a gouty diathesis with a raised blood uric acid? How should one estimate renal function in a case of gout?

A.—The blood uric acid is raised in azotaemic nephritis when renal failure causes retention in the blood of other potential urinary constituents, such as urea. The normal blood uric acid level of 1.5 to 3.5 mg. per 100 ml. may rise to 20 or more, an extreme level being about 30 mg. per 100 ml. (Fishberg, A. M., *Hypertension and Nephritis*, 1939, p. 40). In gout the blood urea is raised only in renal failure, whereas the blood uric acid may be raised when renal function is otherwise normal.

Renal function can be estimated in gout in the following way. If the twenty-four-hour urinary volume is 600 ml. or more and the kidneys can concentrate any single specimen of urine to a specific gravity of 1020 or over, the concentration being encouraged if necessary by a twelve-hour fast, then there is no significant general diminution of renal function no matter what the level of the blood uric acid. Only if the concentrating ability of the kidneys is defective, or the urinary volume is deficient, according to these criteria, is it necessary to estimate the blood urea to learn if retention of potential urinary constituents is occurring.

"General Debility"

Q.—How can so-called "general debility" in the ordinary working-class patient be tackled so as to get the quickest recovery?

A.—The family doctor best serves his working-class clientele by patiently attempting to discover the cause of this "general debility." Common disorders, such as anaemia, tuberculosis, new growth, cardiovascular or renal disease, involuntarily depression—all productive of general debility as a presenting symptom—must be excluded or, if discovered, treated. The doctor must decide what investigations are necessary and justifiable. Minor physical disorders, such as varicose veins, painful feet, prolapse, haemorrhoids, and skin disorders, discovered in the general examination should be treated, since they may have importance as contributors to debility. These things having been accomplished, it is probable that the causes of debility in 10 to 20% of working-class patients will have been revealed. The remaining large majority can be classified thus:

(a) "Poor Frails."—By constitution or by lifelong habit. Encouragement, tonics, and sedatives for decent sleep are the appropriate remedies.

(b) *Psychological Disorders*.—Mainly anxiety states, hysterics (usually chronic, and eradicated only by the expert, if then), depressions, and obsessional states. Mild anxiety states may be treated by listening and by advice; and may be relieved, if the anxiety is about health, as commonly happens, by examination and investigation. Severe depressions should be referred to the expert. Obsessional disorders are usually missed in diagnosis—they lie so near to the average personality of the English and the Scots—and they commonly produce fatigue. Mild cases may be given a holiday with benefit, and persuaded to better courses.

(c) *Environmentally Induced Debility*.—The causes are legion. They include domestic stress, tensions at work, sex troubles, bad habits of feeding and hygiene, inadequate recreation, and so forth. Thoughtful and emphatic advice will sometimes work a miracle in this group.

(d) *Tired Folk*.—Especially the devoted mothers getting to middle age. These are badly short of rest and appreciation—large amounts of both should be provided.

In all four groups it is notable how good a therapeutic result is obtained by the exhibition not of nux vomica but of the doctor's ready interest.

Sulphonamide Prophylaxis of Pneumonia

Q.—Sulphonamides and penicillin are useless against the virus of influenza, but would there be any point in using, say, the former prophylactically against secondary infections? Would it, for example, have any effect on the mortality from pneumonia?

A.—We know of no statistical evidence that the frequency of pneumonia complicating influenza is reduced by prophylactic sulphonamide treatment, although this result is certainly to be expected. There has been no epidemic in recent years in which pneumonia appeared often enough for such proof to be feasible. In an epidemic, the higher the incidence of pneumonia the more clearly would treatment aimed at its prevention be indicated. For fairly mild and usually uncomplicated influenza—the kind we are seeing now—the routine administration of sulphonamides is not indicated. In *The Medical Use of Sulphonamides* (M.R.C. War Memo. No. 10, 2nd ed.) the verdict on this controversial question, applying also to bacterial infections complicating measles and whooping-cough, is: "Experience favours the giving of the drug at the first signs of secondary fever, rather than as a routine prophylactic in every case."

INCOME TAX**Demobilization and Income Tax**

The system under which income tax is deducted from officers' pay is briefly that a central office, that of the income-tax assessor for the Service Department concerned, is responsible for deciding what allowances and reliefs an officer is entitled to and instructing the paying officer accordingly. Bearing in mind the fact that the three Services have been scattered all over the globe and are liable to transfer from one theatre of war to another, it is inevitable that serious difficulty must often arise in the task of seeing that the correct amount of tax has been deducted from pay by the time the last payments have been made. Press comment suggests that in some cases serious hardship may be caused by too drastic attempts to recover after demobilization arrears of tax caused by inadequate actions during service.

The legal position is that the Service pay is assessable by the departmental authority and not by the local Income Tax Commissioners, but the assessments may be made after the termination of the service. In such circumstances, however, there appears to be no essential reason why hardship should be caused; the assessor for the Department concerned can arrange for formal notice of the amount due to be given to the demobilized officer, and collection can presumably proceed with proper regard to the officer's financial circumstances. Judging from references in the press the suggestion is that hardship is apt to arise where the authorities exercise their right, under the Regulations governing the "Pay-as-you-Earn" system, to recover the amount under-deducted by manipulating the "code" applicable to the subsequent civil earnings of employment. It may be of interest to see how this works in practice so far as available information suggests.

Reference was made above to "the correct amount of tax" to be deducted from pay, but in fact there is strictly no specific sum which alone is "correct." A taxpayer is entitled to certain allowances for the financial year, but there is no obligation on the authorities requiring them to spread the total of those allowances equally over the 365 days of the year, and that fact gives a certain elasticity to the assessor's calculations. Suppose, for instance, that an officer's pay ceases two months after the opening of the financial year—e.g., on May 5—and that during those two months he drew £80 in taxable pay and suffered no deduction therefrom. The departmental assessor can, if he chooses, regard that £80 as set off against £80 of the allowances due to the officer, thereby justifying the non-deduction of tax from the pay. In such a case there will be no "arrears," but it follows that tax on the civil earnings will be proportionately higher than it would have been if the £80 had not been absorbed by the two months' pay. That is no doubt a simple and unlikely case, but it illustrates how insufficient deductions during service may react on the deductions to be made from subsequent earnings of civil employment. The converse can, of course, occur; excessive deductions during service should in such cases either be rectified by a refund made direct or produce lower deductions from civil earnings than would otherwise be made.

If a demobilized officer has reason to think that the action, or inaction, of the Department concerned is imposing unreasonable hardship on him or that he has suffered excessive deductions for which redress has not been arranged by one means or another, he would be well advised to request the departmental assessor for a full statement of his tax position, so that he may be satisfied that that matter has been correctly and finally closed.

First Purchase of Car

R. C. has to purchase a car to start work as an "assistant with a view to partnership." Can he claim any deduction?

* Only the 20% initial allowance under the Income Tax Act, 1945, plus (while he acts as an assistant, or in any case after April 5, 1947) the depreciation allowance of 25% on written-down value.

LETTERS, NOTES, ETC.**Disseminated Sclerosis: A Request**

Dr. DOUGLAS McALPINE (Department for Nervous Diseases, Middlesex Hospital) writes: At this hospital a special inquiry into the past history of patients suffering from disseminated sclerosis is being made in the hope that some light may be thrown on the aetiology of this disease. Cases of less than five years' duration are particularly required. The co-operation of general practitioners in the London area would be appreciated. Cases will be seen during a special out-patient session on Friday afternoons by appointment only (Ring MUSEum 8333, Ext. 310).

Coccygodynia or Proctalgia?

Dr. F. M. ROSE (Preston) writes: Dr. T. Astley Cooper (Feb. 2, p. 192) describes a case of what is obviously proctalgia fugax. I cannot find that a reference is made to this condition in Price's *Medicine*, but there is a short note in the *Encyclopaedia of Medicine*, volume X, page 519. The cause of the pain felt over the coccyx is spasm of the levatores ani. I was unacquainted with the condition until I developed it myself, possibly 15 years ago. The pain is probably more in the lower sacral than in the coccygeal area, is usually nocturnal, and is associated with some degree of constipation. Typically it begins as a dull ache which may cause a confused dream, and eventually the victim wakes. He lies for a few minutes hoping that it will pass, but is always forced to go to the lavatory and may pass a small scybalous mass. At this stage the pain grows in intensity and is generally associated with crampy pain over the sigmoid. After some minutes flatus and perhaps a small amount of faecal matter of normal consistency is passed and the pain gradually passes off, leaving the now relieved sufferer very pale and shaken. The condition is not very common, and I can recollect only two or three cases of patients and one of a colleague. One factor in the causation may be the taking of saline aperients on retiring.

Dr. W. B. HOWELL (Brenchley) writes: The condition noted by Dr. T. Astley Cooper suggests that which has been described by several authorities, including the late Sir Arthur Hurst, in recent years. It has been given the name "paroxysmal proctalgia" or "proctalgia fugax." Having experienced several such attacks personally since a severe attack of bacillary dysentery (Flexner) in India four years ago, I imagine that the pain is really a localized ring of spasm in the rectum. I agree that the pain, although vague in distribution to start with, eventually becomes localized in the region of the coccyx; it quickly reaches an agonizing intensity, occasionally accompanied by profuse sweating and breathlessness, and quickly subsides with the passage of a small amount of flatus. This latter phenomenon, I think, supports the rectal spasm as the origin of the pain. Sigmoidoscopy after an attack revealed nothing in my own case but the rather glazed appearance of the rectal mucosa which, I understand, is a common finding after bacillary dysentery. Several writers have noted varying precipitating causes for the condition, such as excessive smoking, threadworms, coitus interruptus, masturbation, etc. Personally, I have noticed that all my attacks have come on after a period of overwork and anxiety, and always at night. Various remedies have been suggested, such as rapid inflation of the rectum with air or water from a Higginson syringe, 3-minim (0.18 c.cm.) chloroform vaporoles, or amyl nitrite capsules. One patient has obtained instantaneous relief by swallowing glucose. Another has found that abstaining from tobacco cures the condition. If an attack follows coitus interruptus or masturbation the cure is obvious. It is important to exclude local disease in the pelvic colon, rectum, and anal canal, so that full reassurance can be given. Without this no other treatment is likely to be successful, as the pain is so unlike any other sensation that one is certain, when first experienced, that this must be the pain of a cancer. I have found that small nightly doses of phenobarbitone or butobarbitone, especially during periods of anxiety, do much to ward off the attacks.

Journals for Hong Kong

Dr. P. S. SELWYN-CLARKE, Director of Medical Services, Hong Kong, writes from the White House, Albany Street, London, N.W.1: I am greatly indebted to you for having published my appeal for medical journals for Hong Kong in your issue of Feb. 9. The response has been so very generous that an adequate number have already come to hand. Until it is possible for me to make individual acknowledgment of these gifts, may I thank the donors very warmly through your columns on behalf of my colleagues in Hong Kong.

Correction

Prof. R. A. PETERS, M.D., F.R.S., writes to point out two slips in the leading article on "BAL" published on Feb. 16. On page 241, line 20 of the first column, it should be "no monothiol or dithio compound." A dithiol compound is not the same as a dithio compound. Secondly, in the same column, line 14, the reference should be "Peters, Sinclair, and Thompson," instead of "Peters, Stocken, and Thompson."

LONDON SATURDAY MARCH 2 1946

THE DIAGNOSIS OF AMOEBIASIS

BY

W. L. KERSHAW, M.B., M.R.C.S.

Surg. Lieut.-Commander, R.N.V.R., Pathologist to a Royal Naval Auxiliary Hospital

Amoebiasis is one of the major problems confronting the Medical Services in the Far East. The incidence is surprisingly high, the diagnosis often difficult and elusive, the treatment unsatisfactory, and the relapse rate disappointing (Payne, 1945). In addition to those whose symptoms are sufficiently incapacitating to lead to admission to hospital, there are probably a greater number of individuals who, after infection, become cyst-passers unaware of their condition and of their gradual deterioration in health and fitness. On final demobilization difficulties will arise in temperate climates not only among those returning from the East but among others who will be infected by them.

The disease is so protean in its manifestations that it is important not only to confirm the clinical diagnosis but, if possible, to eliminate the suspicion of amoebic infection in other conditions which may simulate amoebiasis. Moreover the identification of cyst-passers is of the greatest assistance in preventing its spread. After four years' service in the East one cannot but arrive at the conclusion that the seriousness of amoebiasis has not been fully appreciated in the United Kingdom, nor have the majority of residents in the East been sufficiently alive to the risk of infection to which they may be constantly exposed. It is well known that over 90% of the indigenous population suffer from worm infestation, and the examination of 600 cooks, ward boys, and others handling food in establishments near this hospital showed that 12% were passers of the cysts of the *Entamoeba histolytica*. The danger of infection to which Europeans are exposed is thus considerable. It is possible in the majority of cases to be ignorant of the infection and, even if it be suspected to experience but little interference with normal life. That health has been below normal is volunteered by all cyst-passers—even though they may have been entirely symptom-free—after the completion of treatment. The danger lies not so much in the more dramatic accidents of hepatitis, haemorrhage, or perforation as in the general lowering of health and efficiency.

It is suspected that amoebiasis is a much more common condition among Europeans than is generally realized, and that the failure to appreciate its incidence is due largely to the lack of symptoms distressing enough to cause the patient to seek advice, and partly to the tendency to arrive at a premature negative diagnosis on the results of too few investigations.

Material

These conclusions have been drawn from a series of 300 cases seen in Ceylon in which the *Entamoeba histolytica* has been identified in its vegetative or cystic form. During these investigations some 40,000 stool examinations have been made.

The incidence of amoebiasis in intestinal complaints is surprising, as it forms 46% of the total cases admitted to this hospital.

Cases Admitted with Bowel Disorders

	Per cent
Enteritis	46
Bacillary dysentery	
Proved	7
Clinical	1
Amoebiasis	46

Though the incidence may appear to be high, it can be explained in part by the fact that the majority of cases admitted to this

hospital are referred from other establishments, and thus the acute cases of gastro-enteritis which normally recover within a week or so are not seen the greater proportion consisting of ambulatory cases of old-standing diarrhoea and abdominal pain.

The number of examinations required to arrive at a diagnosis differs from case to case.

Number of Stools	Percentage of Cases Diagnosed
1	30

12	3
Over 12	11

Two large groups occur. One-half are diagnosed on the first 3 examinations and half of the remainder after 8 or 12. The diagnosis of the few remaining usually requires between 16 and 20 examinations. The first group represents cases which show obvious blood and mucus with diarrhoea (25%), and three quarters of the cyst-passers (25%), the second group those with vague abdominal symptoms, whose clinical relapses and admission to hospital are followed by an exacerbation of the pathological process. If the examination of stools is limited to three specimens (Manson Bahr, 1943) a considerable proportion will remain undiagnosed. Even 10 specimens (Svensson and Lerner, 1938) cannot be considered to be adequate. Each case should be judged on its merits, though for routine purposes nine tenths of those in which the *Entamoeba histolytica* may be found will be diagnosed if 12 specimens are examined. Caution similarly should be exercised in assessing the results of treatment.

Attacks of bacillary dysentery and acute enteritis have often brought to light an underlying amoebiasis. It is therefore of as much importance to be able to eliminate the possibility of an amoebic infection as it is to establish the diagnosis. In all cases complaining of diarrhoea, whether the exudate suggests an amoebic, a bacillary, or a mixed origin examinations have been carried out throughout treatment and convalescence in order to eliminate latent amoebiasis and to determine whether any reliable diagnostic criteria could be established. It has been found that in cases of acute bacillary dysentery (Sonne and Flexner) which recover clinically the excretion of red blood cells and leucocytes does not persist for more than two weeks after the onset of the original attack. (An insufficient number of Shiga infections have been encountered to afford any conclusion.) No reliable characteristics have been found to differentiate macrophages from pre-cystic forms of the *Entamoeba histolytica* in unstained films. As the infection progresses, however, it becomes evident that cases fall into two groups: those which subsequently excrete less degenerate and later vegetative *Entamoebae* and which, with their remission, pass pre-cystic forms, and those in which the pathological features disappear gradually, with the entire absence of cysts. It is on this last feature—the disappearance of the red cell—

leucocytes, and macrophages, and the non-appearance of cysts—that underlying amoebiasis may be eliminated.

It has been possible to follow for over a year the progress of some 30 patients, in addition to others exposed to exactly the same risk of infection. An opportunity has thus been provided to compare the findings over a long period with the subsequent clinical history. It is found that no contact whose stools do not contain red blood cells and leucocytes for 10 or 15 specimens shows further pathological features; nor do clinical symptoms develop. Those cases in whose stools red blood cells and leucocytes have appeared after having been absent, perhaps, on three or four examinations have been considered as potential hosts of the *Entamoeba histolytica*, for after purging or on more prolonged examination this infection becomes evident. Twenty-five cases with no clinical symptoms have been diagnosed in this manner.

Identification of the *Entamoeba histolytica*

The pathological diagnosis of intestinal amoebiasis may be considered from two aspects: (1) the recognition of the *Entamoeba histolytica* and its differentiation from other protozoa; (2) the measures which provide the best opportunity for its recognition.

Little need be added to the accepted features; for if the three criteria of size, the ingestion of red blood cells, and purposive movement with the explosive extrusion of pseudopodia are observed, the possibility of confusion with other intestinal protozoa is remote. Although it may be tempting to predict the subsequent development of one of these features which may be absent for the moment, it has been found in this series of cases that to hazard a diagnosis on sluggishly moving or immobile pre-cystic forms is unnecessary; for sooner or later, usually in the three or four subsequent specimens, a definite diagnosis can be made.

Methods for Rendering Discovery Easier

The recognition of cysts has proved to be more difficult than is usually assumed, as the majority have ill-defined characteristics. In direct smears the recognition of chromatoid bodies is no easy matter, and in those stained by Weigert's haematoxylin after fixation in Schaudinn's fluid considerable care should be exercised in the elimination of artifacts. Organisms adhering to the surface of the cyst and plications of the wall from enfolding during fixation may closely resemble the internal structures. To overcome this difficulty a modification of Faust's method of concentrating cysts (Faust *et al.*, 1939) has been used, employing copper sulphate.

A piece of faeces about 4 cm in diameter is macerated with distilled water in a urine glass and allowed to sediment and filter overnight through six layers of surgical gauze. The supernatant fluid is poured off and the faecal mud is mixed with a saturated solution of copper sulphate and centrifuged at high speed for ten minutes. Films are made from the upper surface.

The advantage of this method lies not so much in bringing to light cysts which would not have been seen in direct smears as in that the washed cysts can be seen clearly, for the only bodies which appear with them after concentration are helminth ova and occasional vegetable cells. No confusion of intracellular detail with artifacts can thus arise. The copper sulphate stains the majority of vegetable cells blue and precipitates protein matter. This method of concentration reveals cysts in twice the number discovered by the examination of direct films.

It has been accepted in the past that chance plays a large part in the diagnosis of intestinal amoebiasis. This, however, is not borne out by the findings in this series. The stools are passed and examined under optimum conditions, the bed-pan being dispatched immediately after use and the contents not transferred to a smaller receptacle. The blood and the mucus which may be adherent to the outer surface of the stool are thus retained in this position, and in those cases in which a pultaceous stool is excreted the mucus passed at the end of defaecation is easy to recognize. The delivery of a specimen in a second container, though possibly convenient to a ward, interferes with the easy selection of material for examination. It has been our practice to make four separate slides from each stool, in order to reduce the possibility of error due to random sampling. The appearance of pathological features can be

hastened by a purgative. A saline cathartic is preferable, as oily laxatives leave droplets which obscure the microscopical field. It is important to avoid this measure in the quiescent stage before the undisturbed state of the colon has been ascertained, as it is sufficiently irritant to produce red blood cells and leucocytes.

Each case shows a regular evolution. There is a gradual change in a relapse from normal stools with a very occasional leucocyte to the appearance of red blood cells and leucocytes in greater profusion. Cysts then develop. Later mucus, with more leucocytes and pre-cystic forms, is found, with frank blood. This stage is followed by the appearance of vegetative forms, or the condition subsides in the reverse order after a variable interval. This tide is more or less symmetrical, and if, after the pre-cystic and immobile forms have been found, cysts begin to reappear, the vegetative forms are not to be expected, and a further exacerbation must be awaited or a diagnosis made on the identification of the cysts. This cycle is longer in duration and more gradual in its progress in cases associated with vague abdominal symptoms and is more precipitate in those with diarrhoea. Several volunteers whose course could be followed closely confirmed this conclusion. A graphic representation recording the features of consistency, the presence of macroscopic blood and mucus, and the finding of red blood cells, leucocytes, vegetative, pre-cystic, and cystic forms of the *Entamoeba histolytica* made this contrast between the acute and chronic cases evident. So far as is possible every stool has been examined, but in the acute cases those passed at night have been discarded. In the chronic cases, however, as cysts and not vegetative forms are to be expected, these stools are retained for examination the next day.

The regularity of this rhythm suggests that it represents the pathological activity of one lesion—or, alternatively, that the diseased colon undergoes its relapses and remissions as a whole—rather than the existence of separate lesions with uncorrelated cycles. This is confirmed by the general increase in activity accelerated by an attack of gastro-enteritis or by the use of a purgative.

There is a close correlation between the pathological findings and the site of the disease as assessed on clinical and radiological evidence. In rectal disease—when the chief complaints are diarrhoea, tenesmus, and the passage of frank blood and mucus—red blood cells, leucocytes, and vegetative pre-cystic forms are found, but cysts rarely appear. The vegetative forms, though perhaps immobile when examined at first, may become quite active after half an hour on a warm stage, even after the mucus has been previously immersed in broth at room temperature for the purpose of culture. This suggests that, though care should be taken to ensure that examination is made immediately after evacuation, the interval between the shedding of the amoeba from the ulcer and its discharge per anum is of importance. This factor may be reduced by encouraging the patient not to delay in defaecation or by purgation.

When the caecum and ascending colon are involved, with the production of vague pain and constitutional symptoms, there are no active forms; but cysts, leucocytes, and red blood cells are found more or less uniformly distributed throughout the faeces. Perhaps the reason for this is not so much the differing type of lesion as that in their passage down the colon the more active forms degenerate into cells which may not be recognizable as having been derived from protozoa. The "showering" of cysts does not seem to occur when four specimens are examined from each stool.

Adjuncts to Diagnosis

The value of sigmoidoscopy as an adjunct to diagnosis would seem to depend on the experience of the investigator. In the more obvious cases, in which pathological confirmation of an almost certain clinical diagnosis is required, the findings on sigmoidoscopy are usually definite. A preliminary stool examination to eliminate bacillary dysentery and perhaps to identify the *Entamoeba histolytica* might well be followed by sigmoidoscopy or proctoscopy for the easier collection of mucus. In the obscure cases, in which doubt arises in the pathological findings and in which the elimination of amoebiasis may be of importance, the lesions may be high up or minute. Furthermore, in this series of cases few of those presenting

caecal tumours had ulcers in the rectum or the pelvic colon. This experience is in contrast with that of Payne (1945). Sigmoidoscopy would appear to be of great value in effecting a diagnosis in the dysenteric case in the shortest time but to have limitations in latent cases.

Conclusions and Summary

The prevalent attitude to amoebiasis is concerned with the difficulties of treatment, the liability to infection being regarded as an unavoidable risk. As a feasible and practicable laboratory diagnosis can be made it is felt that attention should be directed to the prevention of its spread by the removal of cyst-passers from the handling of food, the diagnosis of latent cases in permanent residents in the Tropics, and the elimination of unsuspected infection among members of the Services on repatriation.

The pathological findings of 300 cases of amoebiasis in which the *E. histolytica* has been identified are described. The difficulties of laboratory diagnosis are discussed. Routine examinations, to reduce the incidence of the disease, are suggested.

I am indebted to the Medical Director-General of the Navy for permission to publish this paper; to Surg. Capt. T. N. D'Arcy, R.N., and Surg. Capt. F. E. Fitzmaurice, R.N., medical officers in charge of a R.N. auxiliary hospital; to Surg. Lieut.-Cmdr. J. Ronald R.N.A.R., and Surg. Lieut.-Cmdr. E. M. Buzzard, R.N.V.R., medical officers; and to Petty Officer G. W. Wood for technical assistance. I wish to thank Prof. S. L. Baker for his helpful advice and criticism.

ACROPARAESTHESIA IN THE LOWER LIMBS UNEXPLAINED PAINS IN THE LEGS AT NIGHT

BY

J. PURDON MARTIN, M.D., F.R.C.P.

Physician to the National Hospital, Queen Square, Neurologist to the British Postgraduate Medical School, Hammersmith

For simplicity I have used the word "pains" in the subtitle of this note, but the sensation which is experienced in the cases I refer to is not actually pain but a peculiar tingling discomfort which when intense, becomes painful. I believe the sensation is the same as in the condition called acroparaesthesia, which commonly occurs in the arms at night and is of far more frequent incidence in women than in men. Among the early descriptions of it were those of Putnam in 1880 and of Ormerod in 1883, and following the lead of the former, it is still usual to regard it as a vasomotor neurosis; but Behrman (1945) in his recent paper regarded it as due to slight pressure on the brachial plexus at the thoracic inlet, and, while insisting that it was not necessarily nocturnal, attributed its frequent occurrence at night to the influence of the recumbent posture and the hypotonia of sleep in bringing about such pressure. Walshe (1945) has taken a similar view. Acroparaesthesia in the lower limbs has been mentioned by some of those who have written on the subject, but in recent times its occurrence seems to have been insufficiently recognized. All the sufferers from it whom I have encountered have been in men, but one patient said that his mother had suffered from "pains" in the legs which he thought were similar to his own.

The following cases provide good examples of this condition

Case I

An architect aged 68 complained that he had pains in his legs at night, which he had been subject to for more than forty years. They had gradually grown worse as he got older, and now they kept him awake a great deal. The pains used to come on after he had gone to sleep and wakened him up, but recently they had occurred about half an hour after he had got into bed. Formerly he used to move his legs to a cooler part of the bed or put them out from under the blankets, but in recent times these measures have been insufficient, and he has had to get out of bed and walk about the room for a little. He may have to do this several times in one night. If he gets out of bed in this way while the pain is present he may feel "groggy about the ankles," and in the mornings he sometimes feels similarly "groggy." When he came to see me he

said he was getting practically no sleep till three or four o'clock in the morning.

The sensation in his legs began as a tingling in the calves, and gradually, as it became worse, it became more like pain. He called it "neuropathy." The discomfort was always below the knee. In answer to my inquiry he said he had some burning sensation in his feet, but evidently this was not an important feature in his condition. The "pains" were limited to the night, except that very occasionally in winter, when sitting in front of the fire, he had felt some tingling in his calves. Even when he had to stay in bed because of illness the pains were limited to the night, and they had been very troublesome when he had pneumonia, and also after he had had his prostate removed nine or ten years ago. He did not think that his position in bed made any difference to the occurrence of the pains. As an architect he was in the habit of standing all day at his work, but he did not believe that exercise during the day had any influence on the nocturnal pains, because the latter had occurred as usual when he was kept in bed by illness. He was inclined to think that mental strain had more effect in aggravating them than physical exercise. He said he was not a rheumatic person and had no pains elsewhere.

The patient was a thin man of medium height and generally of light build. I found no abnormal physical signs in any part of his nervous system or elsewhere in his body. In particular the knee-jerks and ankle-jerks were normal and the plantar reflexes "flexor." He had no loss of appreciation of light touch, pain, temperature, position of his toes, or vibration. The muscles of his legs were all of normal size and were not tender. He walked normally, and Romberg's sign was negative. His blood pressure was 140/90 mm Hg and his arteries felt normal for his age. There was good pulsation in the dorsalis pedis artery in each foot, and his toes showed no cyanosis or pallor. He had no varicose veins. His heart was normal. His spine seemed normal and he stood in a normal posture. There were no signs of arthritis in his knees or hips, or elsewhere. In his abdomen I found no abnormality. His Wassermann reaction had previously been done, and was negative.

He had had various kinds of physiotherapy to his legs and different types of medical treatment without any benefit resulting. He had also been treated with vitamins B₁ and B₁₂ over a long period, and had been given phenobarbitone at bedtime to make him sleep.

I advised that he should cease standing at his work and prescribed a course of barium 10 gr (65 g) with phenobarbitone 1 gr (65 mg) to be taken at bedtime, and these measures brought about a complete improvement. After ten days he gave up the phenobarbitone and he has continued to have restful nights.

Case II

A doctor of my acquaintance, now aged about 50, has suffered from numbness and pains in his legs at night off and on for about fifteen years. The sensation is an uncomfortable tingling, but it is more or less painful and is associated with some tenderness in his calves. At first the discomfort occurred only after playing tennis, and in recent years it has usually been associated with other forms of physical exercise such as gardening or driving his car long distances. He has long intervals of freedom from his symptoms, and at other times the pain or discomfort may be troublesome every night for weeks. It has gradually become more frequent, its intensity is very variable, but during the war, when he was working very hard and driving about a great deal, there was a period during which it was worse than he had ever experienced before. The discomfort wakens him up about half an hour after he has gone to sleep, and it may awaken him two or three times in a night. If it is not severe he merely puts his legs in a cooler part of the bed, but ordinarily he puts them out from under the bedclothes, and sometimes he lies on his face and holds his feet up in the air and moves them at the ankles so as to exercise his calf muscles. In recent times he has had a mild burning sensation in his feet associated with the "pains," but this burning sensation also occurs independently of them. So far as he has been able to determine, the posture in which he sleeps does not make any difference to the incidence or severity of the symptoms, which occur every night for a time and then remit for weeks or months. He has not observed any influence of psychological factors on the pains, and has been through periods of mental stress without suffering from them. In contrast to the previous patient, he was free from these pains during a period of illness. He never has any active discomfort in the daytime, but when the pains are troublesome he says that he can feel a little tingling in his calves during the day "if he thinks about it," and there may even be a little deep tenderness in his calves.

His ankle-jerks and knee-jerks are quite normal. There has been no wasting of his calf muscles or other musculature, and no loss of sensation or change in the appearance of the skin. The arteries of his feet seem normal and there is no indication of impaired circulation, but when the burning sensation is present some redness is seen along the outer borders of his feet and outer parts of the soles. He has no varicose veins.

He is a tall thin man. Though generally healthy he is somewhat rheumatic, has had nodules on his fingers since his student days, and is liable to occasional pains in his shoulders and hip-joints. His blood pressure is normal. When the pains are troublesome this patient takes 10 gr. of aspirin at bedtime, with invariable relief.

Case III

In another patient whom I saw recently paraesthesiae affected all four limbs; they were not related to exercise and they occurred during the day as well as during the night. He was a butler, aged 57, and had been liable to these abnormal sensations for three years at least. They occurred when he got warm, and affected his hands and forearms and his feet and calves. They were worse if he sat long in one position, unless he was in the cold. During the day he relieved them by avoiding warmth so far as he could and by muscular movements. During the night he "kept looking for a cold spot" for his feet in the bed, or put his feet out from under the bedclothes, and in the summer he was accustomed to lie on top of the bedclothes.

Except that he had some varicose veins I found no abnormal physical signs. His pulse was not abolished at either wrist by putting his shoulders back and taking a deep breath. He had had prolonged treatment with vitamin B without effect on his symptoms.

Other Cases

During the war, while acting as neurologist to the Eastern Command (Home Forces), I saw several cases of this kind in soldiers. I recall two instances in officers, whose symptoms began while they were serving in the Army. They were both men in the middle forties, whose military duties had required them to undergo more strenuous physical exercise than they had been accustomed to in civil life. Both of them attributed the occurrence of the pains to marching, and one said quite definitely that if he did no marching he had no pains. Both had been greatly relieved during periods of sick leave. One had been treated with applications of radiant heat to the legs during the day, but it seemed to me probable that rest was the more important factor in bringing about the improvement. Both of these patients were of stouter build than either of those in the first two cases, and one would undoubtedly be classified as stout. I do not recall details in regard to their liability to rheumatic symptoms or whether they had any varicose veins.

Comments

I do not propose to discuss the differential diagnosis of this condition, which is in general not difficult. It is obvious that it is necessary to make sure that there are no signs of any organic disease of the nervous or vascular system and to exclude pains due to arthritis and sciatica.

The tingling is usually described as being in the muscles, and is relieved by muscular activity, but the burning sensation in the feet, if present, is superficial and is relieved by putting the foot against something cold. Ekholm (1945a, 1945b) considers that there are two varieties—pain and paraesthesia. My own experience does not bear this out. Paraesthesia if sufficiently intense may become painful, and the same subject may suffer at one time from tingling and at another from a painful sensation.

These paraesthesiae or "pains" occurring in the legs at night raise several interesting questions: Are they of the same nature as the acroparaesthesia which is frequent in the upper limbs? Have they an organic cause? What, if any, is the influence of physical exercise in bringing them about, and, if it does, by what mechanism is this delayed effect of exercise produced? Why do they occur during sleep?

There can be little doubt that the sensation is the same as that of acroparaesthesia in the upper limbs, and, in fact, I see no reason why these cases should not be included under the heading of acroparaesthesia, which is one applicable to all the extremities. Schultz (1893), who first used the word "acroparaesthesia," intended it to have this wider application. Not only is the quality of the sensation the same, but both in the upper and in the lower limbs the sensation occurs above all in sleep; if at all severe it awakens the sufferer, and it is relieved by the same means—viz., putting the affected parts out into the cold, holding them up, and exercising them. Furthermore, in very many cases the apparent effect of physical exercise taken during the day in bringing about this peculiar discomfort at night is similar in both instances. Sleep and physical exercise are the most constant associates of acroparaesthesia in the upper limbs, as they are of these paraesthesiae in the lower.

matic conditions (arthritis, fibrositis, Heberden's nodes) are also frequently associated (Parkes Weber, 1945), and similar conditions have been present in some of these cases of "pains" in the lower limbs. Behrman (1945) has stressed the association of the former with pregnancy, but I have not yet observed this association with the discomfort in the legs.

All the cases of acroparaesthesia in the lower limbs that I have seen so far have been in men, and yet acroparaesthesia in general is much more common in women. This contrast can hardly be due to differences of habits and varieties of work between the two sexes. It may conceivably be accounted for by differences of posture and structure in the body, but, if so, no adequate explanation on this basis has yet been put forward. Both Behrman (1945) and Walshe (1945) have attributed the discomfort in the upper limbs in women to a minimal degree of pressure on the structures at the thoracic inlet, but in the cases referred to here I have been unable to discover any mechanical factor to which the paraesthesiae in the lower limbs could be attributed. Posture in bed seems to make little difference, and I have not observed any constant peculiarities of bodily configuration in the individuals concerned. I understand that this variety of discomfort was not uncommon among the officers of our Army in the Middle East, and there was a tendency there to attribute it to sleeping on hard beds. The intermittent character of the symptoms in patients who sleep constantly under the same conditions seems to render a constantly present mechanical cause unlikely, and when paraesthesiae occur in all four limbs it is particularly difficult to suggest any physical mechanism that would account for them.

Similar paraesthesiae in the legs have been one of the most frequent features of the early stages of organic nervous diseases due to dietary deficiencies among prisoners of war, and they occur also in subacute combined degeneration of the spinal cord, polyneuritis, and other organic nervous diseases. Paraesthesiae are also a feature of some cases of vascular occlusion, and they occur in cases of "immersion feet" where there is a combined nervous and vascular effect. But even after forty years of paraesthesiae at night my patient in Case I showed no sign of organic nervous or vascular disease that I could discover, nor have there been such signs in any of my other patients. There is consequently little justification for supposing that in these cases the symptoms represent a minimal degree of some serious organic disease.

The association of these paraesthesiae with exercise seems in many instances to be fairly close; but if they depend in any way upon exercise, why do they occur after such a long interval, and what is the influence of sleep in precipitating their onset? To these questions I am unable to offer any satisfactory answers. With muscular stiffness and other occasional delayed effects of exercise, such as cramps, they do not seem to have any connexion.

The association with sleep is equally puzzling. Acroparaesthesia is one of those conditions which are brought on by sleep and yet terminate sleep or interrupt it. Its dependence on sleep in so many cases seems to be due more to an association with warmth and vasodilatation than with the recumbent posture; but none of these influences is ordinarily effective in the absence of sleep, though in Case III warmth was an adequate exciting cause whether the patient was asleep or awake. It is possible that immobility during sleep is also an important factor. If at all severe the paraesthesiae awaken the sufferer, but if mild they may not do so, and he only becomes conscious of them on waking at about the usual time in the morning.

I have found aspirin (10 gr. (0.65 g.) given at night and/or in the early morning) most serviceable for relieving these paraesthesiae. This is peculiar, because aspirin itself causes vasodilatation and a sensation of warmth and by making him sleep more soundly may increase the patient's immobility; but even if the practice is "homoeopathic" it is justified by the results.

THE PROBLEMS OF DIPHTHERIA*

BY

JAMES GRANT, M.D., D.P.H.

Medical Officer of Health, Gateshead

Diphtheria is of venerable antiquity, but its history really begins with its delineation in 1855 by Bretonneau and Trousseau, who incidentally had previously introduced tracheotomy for laryngeal diphtheria. In 1883 Klebs identified and Loeffler confirmed the causal role of the diphtheria bacillus, and five years later Roux and Yersin demonstrated the exotoxin, which Von Behring used in 1890 to produce an antitoxic serum from guinea-pigs. In 1894 the excellent results with Roux's horse antitoxin in the treatment of diphtheria in Paris brought about the adoption of serotherapy in London, where the customary dosage of 2,000 to 4,000 units of antitoxin subcutaneously produced a fall in the case mortality of diphtheria from 23% in 1894 to roughly 8% in 1905. The principle of passive immunization through a small dose of antitoxic serum was soon established.

Attempts at the active immunization of human beings by injection of toxin finally led to the use of a mixture of toxin and antitoxin for this purpose by Von Behring in 1913, in which year Schick published his famous skin test with diluted toxin. We now know that the presumably susceptible positive reactor has a blood antitoxin content below 0.01 unit per ml., and that antitoxin concentration is above this in the negative reactor.

Some Recent Advances

The use of toxin for prophylaxis has been associated with various disasters, but it has seldom been so used in Britain, where it was shown that injections of toxoid (i.e., toxin altered by interaction with formalin) could confer immunity without toxic effects, although with the risk of local reaction in the sensitive. Further improvements led to our present safe use of alum-precipitated toxoid for children and toxoid-antitoxin floccules for adults.

Although isolated cases of hypertoxic or malignant faucial diphtheria were not unknown, it was reported from Germany in 1927 (Deicher and Agulnik) that an epidemic of severe diphtheria had arisen, that many cases resisted antitoxin treatment, and that there was a suspicion that the antitoxin had failed. Three years later unusually virulent diphtheria in Hull and Leeds was studied by McLeod and his colleagues (1933) who were able to distinguish in 505 clinical cases three distinct strains of diphtheria bacilli, differing in cultural properties. One of these associated with severer cases attended by high mortality (13% and a high incidence of complications (albuminuria 52%, paralysis 20.5%), was named the "gravis" strain and was actually found in 380 of the cases studied. Another strain, found in 102 milder cases of the disease, none of which were fatal, was named the "mitis" strain. Yet another strain, found in 23 cases almost as severe as the first group, had cultural characters midway between the two types named and was therefore called the "intermedius" strain. It now seems that these are five strains and that bacteria having the gravis or intermedius characters are nearly always virulent, while some mitis strains are quite harmless. All virulent strains, however, owe this quality to an identical exotoxin, and most bacteriologists agree that virulent diphtheria bacilli do not lose this property nor do avirulent organisms acquire it.

Originally, diphtheria antitoxin was simply the pooled sera of immunized horses with a concentration of about 500 units per ml. It caused serum reactions in about 40% of patients. In 1925 "concentrated diphtheria antitoxin" was produced, by the removal of useless protein with ammonium sulphate, in strengths of 2,000 units per ml., with a reduction of reactions to 20%. Further digestion of serum protein with enzymes made possible the "refined diphtheria antitoxin" that is used to-day with about 1% of reactions. All along, the standard toxin used in horses to produce antitoxin has been from the Park Williams No. 8 strain, now classified as of intermedius type.

The experiences quoted have thrown some doubt on the efficiency of this strain to evoke an antitoxin suitable for gravis infections and caused some hesitation as to the wisdom of these improvements.

Diphtheria Mortality and Epidemiology

In spite of the fact that in diphtheria the lesion is easily visible, in spite of the unusually accurate and speedy laboratory aid to diagnosis, and in spite of specific antitoxin, an appalling mortality has continued throughout this century, and only three years ago were some signs of improvement observed. As late as 1940 there were 2,465 deaths from diphtheria in England and Wales (Registrar-General's *Stat. Rev.*, 1940). Of small account in infantile mortality the disease caused one-twelfth of the deaths in pre-school children and one-seventh of the deaths in school-children. Until recently this mortality was to be explained only by the lack of timely treatment with antitoxin, and the most common reasons cited for this were the failure of parents to involve medical aid and of practitioners to suspect the disease and administer antitoxin. Neither reason is fully apposite, as we shall presently see.

The official immunization effort began in 1941 and has been well worth while, but in 1944 there were 23,152 cases and 934 deaths. In that year case mortality was 8.4% in pre-school children and 4.7% in younger school-children.

Notification and isolation of diphtheria have been followed for many years, but the disease has scarcely altered in incidence. Contact and carrier immunity to the toxin, act as the reservoir of infection, and survey of the community always show a small percentage of individuals carrying virulent organisms in the throat or nose. When domestic contacts of the disease are studied for the organism, the percentage found to harbour diphtheria bacilli is considerable. Over 10 years, in my own area, 11 and 4 have been the extremes.

The modern view of diphtheria, therefore, is a picture of an epidemic of uninfected carriers proceeding simultaneously with the incidence of clinical cases. Using the Schick test on the population at large, it can be shown that positive Schick reactors diminish from nearly 100% at one year to 10-20% at the end of a decade, and the same has been found true in closed communities. This Schick conversion was actually observed by Dulce and colleagues (1944) in the raw entrants to Greenwich Hospital School during a period of diphtheria prevalence and it is explained as the result of minimal infections with resultant absorption of minute doses of toxin. Diphtheria patients are the susceptible individuals in whom doses of virulent diphtheria bacilli have obtained a foothold.

Spread of diphtheria infection so as to cause the disease or the carrier state must be directly by droplet "spray" or contact and indirectly by infected articles, such as feeding utensils or occasionally milk. Nowadays no one accepts the traditional theories which at one time incriminated defects of drainage or low annual rainfall nor is there any reason to connect the disease with local accumulations of filth. Infection by diphtheria bacilli in a really immune subject is productive of no clinical result, save at the worst the carrier state. In a susceptible person such an implantation nearly always causes a local lesion of which the appearance and pathological sequelae will vary according to the invasiveness of the organisms and their toxigenicity, as modified by the site of invasion and the resistance of the individual and his tissues to the bacilli and to the toxin.

The bacilli appear to favour, in order of preference, the fauces, larynx, nose, genitals, wounds, and eye as sites for entry; but the toxin would appear to be most readily absorbed from the nasopharynx, pharynx, and tonsils, in that order, very little absorption taking place from the skin or anterior nares. The affected area develops a layer of fibinous exudate called "false membrane," on and below which the bacilli multiply. The larger the area of false membrane the more toxin is elaborated. Some other morbid process—e.g., enlarged tonsils and adenoids—may predispose to actual infection, and long after the toxic phase has been combated may allow the bacilli to thrive locally.

The toxin causes local necrosis and oedema and degenerative changes in the tissues, especially the heart muscle, kidney, liver, suprarenal medulla, and peripheral nerves. The natural

*An abridged version of an address to the North of England Branch of the British Medical Association, at the Royal Victoria Infirmary, Newcastle, Oct. 18, 1945.

constitutional reaction to toxin in non-lethal doses is the formation of antitoxin and its circulation in the blood, but this is a very slow process in the susceptible person. If there is some basic antitoxin—i.e., if an antitoxin-producing mechanism already exists—the rate of production of antitoxin will be found accelerated, and this ability to mobilize antitoxin is the best defence against clinical sequels to infection. Natural antitoxic immunity has been shown to increase with age, but it can be set up and stimulated by injections of toxoid, which is the rationale of the immunization process, of the success of which the usual criterion is the conversion of a Schick-positive reaction to a negative.

Carriers are normally Schick-negative, which means that they are protected by natural antitoxin. Convalescent patients have considerable quantities of horse and natural antitoxin in the blood, yet they continue to carry the organisms for varying periods. These facts argue the existence of antibacterial as well as antitoxic immunity.

Clinical Forms of Diphtheria

Faucial diphtheria may be subdivided into tonsillar, pharyngeal, and nasopharyngeal varieties, and it has been usual to describe the disease as beginning on the tonsils and spreading to the palate, uvula, pharyngeal wall, and nasopharynx on succeeding days. Thus a mild tonsillar diphtheria used to be considered a first- or second-day lesion, while nasopharyngeal diphtheria was commonly believed to be of late development and usually accompanied by marked fetor oris, swelling, and distortion of the fauces, with glandular enlargement at the angle of the jaw.

In 1936 severe diphtheria started in Gateshead, its first victim being a general practitioner. It is still prevalent, and many hypertoxic clinical cases have been encountered. I would describe a typical case as follows:

On the first day there is the gradual appearance of some exudate on the tonsil, with translucent oedema of the pillars of the fauces and the palate (an appearance like quinsy but for the absence of three of the classic signs of inflammation). On the second day oedema is more extreme and there is a continuous thin gelatinous film with an advancing edge. At this stage there arises oedema of the associated neck glands, spreading to the periglandular tissues. With treatment the spread of membrane will be arrested—not at once, but in one to three days—and it will show a definite edge and thickening so as to resemble the icing on a cake. Later still it may peel off in one large piece or, as the oedema gradually subsides, shrivel and disintegrate, but the lesion continues to manifest exudate for some days. These changes have often been observed to occur after the administration of antitoxin in doses of 80,000 to 100,000 units intravenously or intramuscularly as early as the second day, and have even been followed by a fatal issue despite this.

In the beginning, gravis infections accounted for half of the Gateshead cases, but since 1941 they have been associated with 80%. I must make it clear that many gravis infections were clinically mild, but also that the severe cases were associated with gravis organisms.

The special features of gravis diphtheria I would summarize as follows: (a) invasiveness and toxicity of the bacteria; (b) resistance to early antitoxin treatment; (c) tendency to produce clinical diphtheria in subjects ordinarily considered to be immune—i.e., inoculated persons, Schick-negative reactors, and persons who have already survived an attack of diphtheria; (d) rare association with laryngeal disease: in Gateshead we have had no tracheotomies in the last three years in 900 cases, while in the earlier years they numbered 1% of cases.

The fatalities of faucial diphtheria are mainly to be found in the severe nasopharyngeal varieties, in which, in addition to faucial membrane, nasal discharge or obstruction and a gagging of the voice occur.

A variety of nasopharyngeal diphtheria, fortunately uncommon, may follow the unusual invasion of the nasopharynx, giving rise to an early nasal obstruction and a later spread of membrane downwards and forwards to the pharynx and tonsils, so as to produce the anomaly of early membrane on the tonsil with marked fetor and toxæmia of several days. Of great importance in faucial diphtheria are the comparative painlessness and relative mildness of early symptoms, best described as degrees of malaise. We should therefore never omit the examination of the throat in an ailing child.

The recognized teaching in suspected faucial diphtheria used to be the immediate administration of a safeguarding dose of 2,000 units of antitoxin and the taking of a swab for bacteriological diagnosis. Even with a warning as to the not infrequent failure of swab diagnosis, this teaching is simply not good enough. The proper procedure is to reserve the expectant attitude for the doubtful tonsillar condition. If the membrane and exudate extend to the soft palate or uvula, if there is any painless swelling of tonsils or fauces or neck glands, if there is fetor, if there is nasal or laryngeal involvement, the case should be sent immediately into hospital as clinical diphtheria, with or without a large dose of antitoxin according to the speed of transport facilities.

In diphtheria of the larynx, occurring primarily or as a secondary spread from faucial disease, strangulation is threatened from the beginning. The earliest sign is the typical cough, succeeded shortly by the suppression of the voice to a whisper and the appearance of inspiratory and expiratory stridor. Every case presenting these three signs should be in hospital and have the benefit of a therapeutic dose of antitoxin while the bacteriology is being explored. A certain number of suspected "croup" will turn out to be non-diphtheritic, and these cases should forthwith be immunized.

Anterior nasal diphtheria is so mild that it is usually found in the examination of contacts. It is to be suspected in excoriations of either or both nostrils with a serous or mucopurulent discharge from the nose, within which membrane may be visible. So common are diphtheroids in the nose that bacteriological diagnosis must always be confirmed by a virulence test. Vulvovaginal diphtheria has, in my experience, coexisted with faucial or nasal infection or disease, and is characterized by membrane on the labia or within the vagina. A feature of both anterior nasal and vulvovaginal diphtheria is the appearance on the skin surrounding the lesion of septic spots, which after serotherapy will be found to retrogress in keeping with the main lesion. Other forms of diphtheria—conjunctival, which threatens vision, cutaneous, and wound—are rare in this country, and their diagnosis necessitates a confirmatory virulence test. Mixed types of diphtheria may coexist in the same patient, and the outlook then depends entirely on the degree of faucial involvement or of laryngeal obstruction, for these are the varieties attended by fatality.

Serious Complications of Diphtheria

The threat to life in faucial diphtheria is limited to the severer forms with abundance of membrane. Thus in 200 cases of nasopharyngeal disease in Gateshead in 1941-4 there were 56 deaths, compared with 884 cases of tonsillar diphtheria with 2 deaths from the disease. Another high fatality rate encountered was 4 deaths among 16 mixed faucial and laryngeal cases.

Death in diphtheria most commonly takes the form of a cardiotoxic syndrome peculiar to the disease. With patients who have not had specific treatment, and may even have been ambulatory, death may be sudden, as was the case in five children found dead at home in Gateshead during the last nine years. More commonly, in hospital, with the patient under treatment by absolute rest in the "head down" position and receiving every nursing attention, the syndrome is of gradual development and may be delayed as long as two weeks. A typical sequence of events is that the toxic patient develops some albuminuria, some tachycardia, accompanied by a softness of the pulse and a waxy appearance of the skin or slight cyanosis. He vomits, and the pulse—sometimes fast, sometimes slow—will show an easily perceived irregularity of rhythm and force. Vomiting is repeated whenever anything is given by the mouth, and there develops thirst with restlessness and mental dulling. The urine becomes scanty and often shows the presence of blood, while there may be widespread skin haemorrhages as in one-fifth of our fatal Gateshead cases. Once vomiting is repeated death is inevitable, and there is no treatment known to me that will save life, although the final issue may be delayed for as long as a week. Other cardiac disturbances, such as extrasystoles and bradycardia, may also be encountered, but in these cases the prognosis is good with rest, so long as the patient does not vomit. The danger of death in laryngeal diphtheria is from asphyxia, and this danger is not entirely removed by tracheotomy, because of the formation of membrane below the incision and the risk of pneumonia.

Although the acute stage may be safely surmounted it is still possible for paralysis to occur, varying in incidence and extent directly with the severity of the acute stage, from a mere muffling of the voice in the mild cases to the development in the more severe of complete paralysis of the pharyngeal and laryngeal muscles and a resultant nasal regurgitation of fluids, inability to swallow, and accumulation of mucus. The paralysis may progress to affect the laryngeal muscles, the diaphragm, and the muscles of the limbs. Very often the muscles of the face are involved and sometimes, indeed, paralysis of accommodation may be the only symptom. In these cases knee-jerks are usually absent. Theories as to causation favour an ascending neuritis from the lesion to the medullary nuclei with a central degeneration of grey matter spreading therefrom upwards and downwards.

Danger to life in paralytic cases chiefly arises from a second form of heart failure which may be sudden but is due to myocarditis and associated degenerative nervous lesions. Gross irregularities of the heart are usual, but there may be no vomiting.

In diphtheria one cannot forecast paralysis in any case nor take steps to combat it. Many patients may emerge through the early toxic stage of severe nasopharyngeal disease to make a rapid and perfect recovery, while other cases of moderate severity, well dosed with antitoxin may show fairly severe paralysis. Nevertheless, the more severe the disease and the sooner the patient the more frequent the paralysis which is most common at about four weeks, but may be as late as the sixth week. It is not uncommon for patients who have undergone hospital treatment for mild diphtheria to be presented shortly after discharge to the family doctor with muffled speech or difficulty in swallowing, and occasionally these are the first intimation that the patient has survived an attack of the disease. For paralysis, only rest, nursing, and vis medicatrix naturae are of avail, but a little strychnine may help.

Treatment

The specific treatment of diphtheria remains, as in the days of Roux, the injection of horse antitoxin or its active fraction. With the use of refined diphtheria antitoxin the danger of fatal anaphylaxis may be dismissed entirely, providing the routine practice is followed of injecting 0.1 ml. of antitoxin subcutaneously and waiting twenty minutes. In the asthmatic or hay fever subject a skin-sensitivity test with the same dose should be substituted. In the absence of any reaction it is fairly safe to administer antitoxin either intravenously or intramuscularly, but adrenaline should be instantly available. Dosage of therapeutic antitoxin continues to be controversial, but it has been established that 1,000 units will confer passive immunity for a period of ten days. In treatment, the small doses of the pioneers by the subcutaneous route were beginning to be replaced just before the last war by doses of up to 30,000 units intramuscularly in severe and late cases, yet such an authority as Ker (Banks 1934) held that the administration of antitoxin in excess of 6,000 units was wasted. In 1928 Goodall had arrived at a similar conclusion about antitoxin in excess of 30,000 units. In 1922 Von Bie advocated a dosage of over 200,000 units in late cases and in 1928 Banks was advocating doses of his order intravenously.

What is the purpose of antitoxin in treatment? Goodall (1928) answered that the object was primarily to neutralize toxin already formed or in process of formation and, secondly, to prevent extension of false membrane. By such a rule, adequacy of dosage could be checked against the local lesion by inspection.

Previous to 1930 the administration of the accepted scheme of dosage, which varied from 16,000 units for the tonsillar case to 30,000 units for the nasopharyngeal, did usually stop the further extension of false membrane, but in severe cases associated with gravis organisms the tendency of membrane to spread after curative antitoxin is marked as are the fatality of the disease and the high incidence of complications.

With the advent of this type of diphtheria the objectives of antitoxin treatment must be restated. To neutralize all toxin already in circulation or being produced at the lesion requires only a comparatively small dose of antitoxin. Ehrlich's original calculation led him to suggest a dosage of about 2,000 units for

this purpose. Certain it is that the injection of 10,000 units will ultimately produce in the average child an antitoxin concentration of somewhere about 1 unit per ml. of blood which is well above the Schick level. We must now view the further objective of antitoxin therapy as the attempt to dislocate toxin already in loose combination with the tissues by providing an excess of antitoxin, and to determine the adequate dose once must meantime rely on clinical opinion. The consensus of opinion is that doses of 60,000 units or upward are required for hypervirulent diphtheria of the kind described. My personal preference in such cases is for a minimum dosage of 80,000 to 100,000 units, but I must say that I am still not satisfied with the therapeutic effects. It is worth of note that an "avid" antitoxin serum—that is, one of unusual combining power—has given satisfaction to McSweeney (1941).

Where gravis diphtheria prevails I would advise the minimum dosage of antitoxin for the suspected tonsillar case to be 10,000 units, 20,000 to 40,000 units for the proved tonsillar or pharyngeal lesion and 80,000 units as a minimum where there is oedema of the fauces, a spreading membrane, or nasal or glandular involvement. In laryngeal diphtheria, so rarely associated with gravis organisms, 20,000 to 40,000 units should be enough and in all other forms—e.g., nasal diphtheria—10,000 units should be ample.

The theory of mixed infection has been responsible for alternative or additional methods of specific treatment for diphtheria but I have used and abandoned streptococcal antitoxin, *C. welchii* antitoxin, and the sulphoramides. Diphtheria bacilli are sensitive to penicillin, and at present we limit its use to severe cases. Its role in treatment would seem to be as an adjuvant for it arrests the formation of membrane and hastens its disintegration but it does not abort the toxic changes.

Diphtheria Prophylaxis

The absence or presence of gravis diphtheria explains the diverse experiences of diphtheria prophylaxis. In North-East England comparative incidence rates show a reduction to one-half or one-third only as a result of full inoculation. There is nevertheless an agreement that mortality is rare in the fully inoculated and in England and Wales deaths from diphtheria have dropped each year, from 2,641 in 1941 to 934 in 1944. Our case-note comparison has been 7 fully inoculated cases to 10 unvaccinated in 1943 and to every 15 in 1944.

What are these cases of diphtheria in the inoculated like? As set out in the accompanying Table, which compares three categories, the mitigation of the disease as a result of inoculation is small, and the only additional note that is called for is that tonsillar disease in the inoculated may give rise to difficulty of diagnosis due to a frequent resemblance to follicular tonsillitis as pointed out by Neubauer (1943).

Clinical Classification of Diphtheria at Gateshead 1941-4

	No. Inoculated	Fully Inoculated	Partly Inoculated
All cases	1	—	1
Tonsillar	613 (61 deaths*)	201	1
Pharyngeal	10 (2 deaths)	2	—
Nasopharyngeal	171 (52 deaths)	16 (1 death)	13 (7 deaths)
Primary glandular	11	—	1
False and other lesions	25 (4 deaths)	—	1
Total	945 (61 deaths)	245 (1 death)	131 (8 deaths)
Hypervirulent cases	—	—	—
Antitoxin cases	164 (17%)	16 (6%)	7 (5%)
Paralysis	50 (10%)	4 (1%)	2 (2%)

* One of these was due to infection in a child who had been vaccinated.

Should these cases of diphtheria in the fully inoculated be given antitoxin? I would answer "Yes," but usually a dose of about 10,000 units. Occasionally we have found that the information as to previous inoculation has not been verified, and therefore clinical rules for treatment should always be followed. Diphtheria in Schick-negative reactors is mild, as it is also in the form of a second attack, of which some 26 cases have been encountered in Gateshead.

We shall apparently not control the incidence of diphtheria by inoculation of toxoid if gravis strains of diphtheria bacilli are prevalent, although we should eliminate mortality. If this is so will gravis diphtheria oust all other strains as a result of

immunization? This one cannot answer finally, but it is an eventuality to be feared, with its great risk for the young un inoculated child.

Comparing methods of prophylaxis, the present dosage of 0.2 ml. and 0.5 ml. of A.P.T. emerges as the best procedure, followed closely by the use of three 1-ml. doses of T.A.F. The smaller doses of 0.1 ml. and 0.3 ml., and latterly 0.1 ml. and 0.5 ml., of A.P.T. seem somewhat inadequate, and the fatal fully inoculated Gateshead case actually received 0.1 ml. and 0.3 ml. of A.P.T. It is possible to establish active immunity by injection of toxoid while the subject is protected with the passive immunity of a small dose of antitoxin.

The duration of immunity apparently depends on the factor of individual variation, which can never be accurately assessed. Nevertheless once antitoxin has been established it may easily be stimulated anew, and the practical application of this is the recommendation to administer 0.5 ml. of A.P.T. to the previously immunized entrant school-child. As mortality from diphtheria really begins in the third year of life, prophylaxis should always be sought in the second year of life, preferably at the beginning.

Contacts and Carriers

Contact carriers present a problem of disposal. In Gateshead we have been content to exclude them from school and work and keep them under observation. Most are carriers for very short periods, but occasionally one encounters the more chronic type. For these individuals hospital treatment is a waste of beds. In some areas swabbing of contacts has been abandoned and the emphasis placed on prophylaxis, but there is one justification for the routine swabbing of contacts in the discovery of a number of early cases of the disease. It is difficult to keep people under observation for the carrier condition without doing something for them, and some local antiseptic treatment has been adopted, such as throat paints in tonsillar cases and nasal insufflations. Lately the Kromayer lamp has been used to irradiate tonsils. In the chronic carrier it is always wise to assess the organisms for virulence before proceeding to surgical measures, such as tonsillectomy, and it looks also as if penicillin should be tried when it becomes available.

Does immunization increase the carrier percentage? The answer is "No," although the immunized person tends to become a carrier if the bacilli gain a lodgment in his tissues.

Conclusion

It must be obvious that we have not yet succeeded in our warfare against diphtheria, although we have made remarkable progress. Our future attack must be along two lines. We have to make our immunization against diphtheria more effective, either by exploring and stimulating the antibacterial defences of the tissues or by perfecting the means of evoking full antitoxic immunity in the body. Our second line demands a more intimate knowledge of the tissue combination with diphtheria toxin, especially in relation to the heart muscle and the nervous system. It also demands a reassessment of the role of the specific antitoxin in relation to this interaction of tissue and toxin. Such an inquiry must keep in view possible differences between the natural disease in humans and that induced in laboratory animals.

With a fuller understanding of the problem than we now possess it may be possible to improve our serotherapy so as to abort the cardiotoxic and paralytic syndromes and perhaps even to treat them along specific lines. The fact that diphtheria very seldom leaves any permanent disability in those who survive, no matter how ill the patient, shows that the tissue damage inflicted by the diphtheria toxin is not necessarily final and irremediable.

The solution of our present difficulties must come from clinicians, pathologists, serologists, and bacteriologists working in the close liaison of the team.

PREFRONTAL LEUCOTOMY IN TREATMENT OF POST-ENCEPHALITIC CONDUCT DISORDER

BY

F. T. THORPE, M.R.C.S., D.P.M.

Wadsley Mental Hospital, Sheffield

There can be few more difficult or tragic cases of juvenile delinquency than those conduct disorders arising from the ravages of epidemic encephalitis, and, although it is 20 years since the last major epidemic, many of the more severe cases continue to spend years of turbulent isolation in our mental hospitals, defying all attempts at re-education. The mental sequelae of encephalitis seem to have transformed these patients into veritable "little devils" with *apache* propensities characterized by uncontrollable and vicious impulses uninfluenced by ordinary disciplinary measures, and their abnormal conduct ranges from excessive naughtiness to gross criminal acts.

In a study of a group of 144 severe cases Gibbs (1930) found that, over a period of eight years of special training, only 8 cases could be discharged recovered, and he considered that the outcome for the majority of the remainder was very gloomy. He concluded that the fundamental cause of much of their abnormal behaviour was an emotional dysfunction, a state of tension or irritability of affect, driving them to periodic outbursts of impulsive conduct of characteristic simplicity, unpremeditated and unplanned. Such a state of affairs would appear to afford the clearest indication for prefrontal leucotomy, which has alleviated many emotional psychotic states by the surgical division of the fibre connexions between the thalamus and the prefrontal area of the brain, thereby reducing the emotional tension. In the words of Freeman and Watts (1944), "Once the emotional nucleus has been successfully abolished, the sting drawn, the reconstruction of the personality can be attempted."

The present paper records two adult cases of post-encephalitic Parkinsonism in which severe behaviour disturbances present from childhood have been removed by prefrontal leucotomy, leaving immature but socially acceptable personalities.

Case I

This patient, a man aged 28, had an insomnic type of encephalitis in 1924, when 7 years old. Previously a normal healthy boy, he became restless and hyperactive, turning somersaults, whistling, noisy at night, and disturbing the neighbours. After a period of 26 weeks in hospital he returned home with little change in his conduct, and he became a constant source of trouble to his parents during the next seven years. He was mischievous and impulsively violent, and he would suddenly hit out without warning. He stole from shops and school, and was on probation for two years. School attendance was spasmodic, and at 14 he started work but was too erratic to continue. Nothing could be done with him, and in 1931 he was certified and sent into the mental hospital.

For the next thirteen years his conduct was similar to that at home. He was irritable, impulsive, and violent, stating that he *couldn't stop himself*. If he happened to be near a window he would suddenly put his fist through it. He once pushed his head through a window. On another occasion he threw a knife at a patient. He would become angry at the least provocation.

A slight degree of Parkinsonism was apparent on admission, and has shown little change during the years in hospital. He has the typical facies and gait, and a slight degree of generalized rigidity, but is very active and otherwise healthy. His intelligence grading was dull and backward, with a mental age of 8 or 9 years on the progressive matrices test. He was the firstborn of four children in a working-class family, and no factor other than the encephalitis could account for his change of conduct.

Operation.—Bilateral prefrontal leucotomy was performed by Mr. J. Hardman, neurosurgeon, Sheffield Infirmary and Hospital, in January, 1944. Under local analgesia after omnopon and scopolamine, a burr-hole was placed 3 cm. behind the orbital margin and 6 cm. above the zygoma. A brain needle was introduced and carried through an arc upwards and downwards to section the subcortical fibres in the plane of the coronal suture just anterior to the tip of the lateral ventricle (McKissock, 1943).

The patient was quiet throughout the operation, and afterwards remained in a dull and stuporous state for two weeks, lying in bed with his eyes closed but easily roused for feeding and attention. He was incontinent of urine. During the next three months he made

rapid progress, and soon regained his former alertness. He is now cheerful and contented, eager to co-operate in the rehabilitation programme. Incontinence gradually lessened, but it has never disappeared entirely. His impulsive and violent conduct has been entirely abolished, and during the two years following the operation he has not once attacked anyone or broken a window. He is now of a quiet and cheerful temperament, and appreciates that he can sit by a window without fear of pushing his fist through it (only the scars on his hands serve to remind him of his former misdeeds). He has been on leave many times and returns to hospital without a fuss. His parents report that, although he no longer has violent outbursts, he is impetuous and not easily diverted from a course of action. He is selfish, and is indifferent to conventional good manners. He is careless in his attire, and will no doubt require a still longer period of habit training before he can take a place in a home environment.

He is handicapped by an intellectual as well as an educational defect due to retardation by the encephalitic process in childhood. A recent psychometric report by Mr E. V. G. Bradford gives him a mental age of 11 years, scored as follows: Shipley vocabulary, 12, Shipley abstraction test, 10, problems, 11, mechanical reading (Burt) 13, verbal repetition, 10, Kohs' blocks 10, cube construction 10. This shows a fairly even performance on a variety of tests, but there was a noticeable lack of sustained attention, and he was not easily satisfied with the results. Nevertheless, it is doubtful if he could have done as well before the operation, although his interest in reading has fallen off considerably since.

His Parkinsonism has remained unchanged, but he has had three epileptic attacks since the operation, and it is noted in the case records that a fit occurred in 1932. This suggests that he has an epileptoid disposition which has been activated by the operation. Unfortunately, electro-encephalography was not available.

Case II

This patient, a woman aged 31, had an attack of encephalitis lethargica in 1924 at the age of 10. The main feature of this attack was sleepiness during the daytime, and she remained in hospital for four weeks. The parents state that on the day of her return home she began fighting with other children, which was unusual for her as she was formerly of even temper. From then onwards she developed temper tantrums, screaming attacks and destructive impulses. She smashed windows and broke crockery, and her parents were continually embarrassed by complaints from neighbours regarding her assaultive tendencies. She said the other girls tormented her. She told lies, but did not steal or show any sexual tendencies. School attendance was intermittent, and from 14 years onwards she remained at home until 21, when she became unmanageable, and was admitted to the mental hospital under certificate in 1936. She was the elder of two children, and no social-environmental factors could be found likely to influence the development of her conduct disorder.

In the first eight years of her stay in hospital she had frequent emotional outbursts often lasting a week or more. She was then violent, aggressive and destructive. Quiet periods became less frequent, and she was always irritable, excusing herself by saying that other people got her 'ratty'. She would not concentrate on intelligence tests, and her score on the progressive matrices, sets A, B, and C, was only 15. Slight Parkinsonism was shown by the facial expression and the posture of the fingers of the left hand with occasional slight tremor. The pupils were irregular and failed to react to light. There was no noticeable muscular rigidity. This degree of Parkinsonism has not progressed much since admission. Menstruation was normal, but did not start until the age of 18. Electric convulsion therapy was attempted in 1944 with little effect, and she refused to complete a course of treatment.

Operation.—Bilateral prefrontal leucotomy was carried out by Mr J. Hardman in November, 1944, using the same technique as before, under local analgesia. She was a trifle apprehensive and emotional during the operation, but afterwards was noticeably calm and placid. On return to the ward there was little disturbance of consciousness, her attitude being one of watchfulness and expectancy. There was no incontinence of urine, and in a week she was up and about, somewhat irritable at first; but after a month she settled down calmly to the hospital routine, showing none of her former angry outbursts.

During the past 14 months she has remained in an even temper, willing and co-operative in simple daily tasks, contented, and apparently quite satisfied with life. Whereas before the operation she was never stable for long enough to permit even a day's leave from hospital, she has now been home on many occasions and returns quite willingly. Her mother reports that when at home she is somewhat impetuous and self-willed, keen to have her own way, and seems unable to concentrate for any length of time. She will, however, read a book for long periods.

A psychometric examination by Mr Bradford resulted in a mental age of 12 years, scored on the various tests as follows: Shipley

vocabulary, 14, Shipley abstraction test, 10, problems, 10, mechanical reading (Burt), 13, verbal repetition, 12, Kohs' blocks, 13, cube construction, 11. As with the first case, the patient showed wide haziness and a lack of sustained attention. Her score on the progressive matrices had increased from 15 to 20.

Comment

There can be no doubt that both patients have benefited by the operation, and enough time has now elapsed to justify an optimistic view of the stability of the results. Both are contented and happy, they had willingly consented to the operation, realizing that it was an attempt to help them to control their temper and violent outbursts. They have both made satisfactory adjustments within the sheltered life of the hospital, yet enjoy frequent visits to their families. Their parents are grateful, and the work of the nursing staff in regard to their supervision is now a pleasure. They are still irresponsible, however, as judged by normal social standards, but this is only to be expected, since leucotomy cannot give them personal attainments they never possessed. They have never been responsible citizens and their personalities were still undeveloped when they were stricken with epidemic encephalitis. Although not mentally defective, they are below the average in intelligence and education, and it is doubtful if they will ever achieve full responsibility. Their capacity to learn may always be limited, but after 20 years of gross maladaptation we are satisfied with a reasonable degree of mental stability and a possible chance of continued development of their personalities.

It is recognized that the best results from leucotomy are to be obtained in individuals who have had well-integrated personalities. These subjects are often able to resume their former occupations and ordinary test of intelligence have, in uncomplicated cases, failed to reveal any special defect which could be attributed to the operation. This is borne out by our two patients who show no appreciable degree of intellectual defect on all our tests given and their present social adjustment would be due to the virus than to the surgery.

Ten years have elapsed since Moriz (1926) conceived of leucotomy for the relief of abnormal mental states, and although success has been achieved in the alleviation of many cases of symptoms in otherwise incurable psychoses, the amount of evidence has accumulated to suggest that the essential part of the operation consists in the interruption of fibre connections between the hypothalamus, the thalamus, and the orbital areas of the prefrontal lobes, which in effect brings about a diminution in the emotional tension or irritability responsible for these symptoms. In this respect it is of interest to recall that William James (1901) maintained that the best proof of his theory of the emotions (that the immediate cause of the emotion is the physical effect on the nerves) lay in those pathological cases, found in every asylum, in which obstacles to emotion leads to unmovable fear, anger, melancholia, or contentment. He might have welcomed leucotomy in support of his theory, for it may well be that, by the surgical interruption of affective-conative pathways, autonomic reactions are so modified that coarser emotions like anger and fear lose much of their intensity. Evidence of this is suggested by the finding of Reiman (1945) that the leucotomized patient shows a diminished response to autonomic stimuli.

Prefrontal leucotomy has already proved beneficial in the epileptic conduct disorders (Ström-Olsen *et al.*, 1943), and it is well known that emotional irritability is a characteristic feature of most of the psychopathic behaviour symptomatic of organic brain disease. It is questionable, however, whether the operation would be of equal benefit in the aggressive constitution: psychopath, since the morbid disposition in these cases is due to an innate or developmental imbalance of instinctive trend. Emotional tension is unusual, and many cases respond to psychotherapy and re-education.

Summary

Bilateral prefrontal leucotomy has been performed on two cases of post-encephalitic conduct disorder of 20 years' duration as present since childhood.

Complete alleviation of the aggressive and impulsive trends was produced in both cases, and has been well maintained over a period of two years and fourteen months respectively.

I am indebted to Sir Arthur Hall for much encouragement and advice.

PENICILLIN IN GONORRHOEA

THE SINGLE-INJECTION METHOD

BY

ALASTAIR ALLAN, M.B., Ch.B., D.P.H.

Deputy M.O.H., Burgh and Port of Greenock

One of my main problems in the treatment of venereal disease in the Port of the Clyde was to cure, or at least render non-infectious, merchant seamen as speedily as possible. Many of those men by necessity of war conditions were able to attend only on one visit or two at most. Continuation of treatment was therefore very problematical. Some men were permitted to stay ashore the requisite length of time, but most seamen were reluctant to take advantage of this. It therefore became necessary to find a rapid method of curing men with gonorrhoea, or rendering them non-infectious, and with this in view a routine treatment of one single intramuscular injection of 200,000 units of penicillin was given. Very acute infections received 300,000 units. Concurrent urethral irrigations were also given if the seaman could attend; if not, their use on board ship was advised.

The supply of penicillin for this purpose was made available to me only in the last few months of the war, and in only 30 cases has enough time elapsed after treatment for a reasoned opinion to be formed of the efficacy of the method. Nevertheless I venture to put forward this small series for two reasons. (1) With the hope that, in some clinic dealing with larger numbers and where patients can be under more continuous supervision, the single-injection method will be tried out on enough cases to provide accurate statistics. (2) The present method of estimating the potent concentration of penicillin in the blood is too coarse—at least, so far as the gonococcus is concerned. The quantity of penicillin required to inhibit growth on artificial media can only roughly approximate to that required to inhibit growth *in vivo*.

Most of the early work on the penicillin treatment of gonorrhoea has been done by American workers. Uniformly good results are claimed in new and old cases, failed sulphonamide cases, and in articular gonococcal infections. All writers stress the importance of maintaining an adequate level of penicillin in the blood. Schemes for repeated injections vary in detail but are identical in principle—intramuscular or intravenous injections repeated at intervals of two or three hours. This undoubtedly maintains a definitely demonstrable level of penicillin in the blood. The same result can, of course, be reached by continuous intramuscular or intravenous drip, but this is hardly justified in gonorrhoea, for which out-patient treatment is a major consideration.

The Literature Reviewed

References to the use of penicillin in gonorrhoea are already voluminous, especially in American literature, but I here refer mainly to recent British medical literature.

McLachlan (1945) recommends 150,000 Oxford units administered in 5 doses of 30,000 units three-hourly, and reports it curative in "nearly all" cases; the gonococci disappear in two to four hours, and the discharge rapidly becomes mucoid and is often absent after 12 to 24 hours. Any cases failing to respond clear up with 100,000 or 150,000 units on the following day.

Harrison (1945) says penicillin is now the first line of attack in gonorrhoeal infections. He recommends 5 doses of 30,000 units two-hourly. Lloyd Jones and Maitland (1945) believe that the serum concentration must be such that a serum dilution of one in eight gives "serum inhibition," and recommend 5 doses of 30,000 units two-hourly. Lloyd Jones, Maitland, and

Allen (*Lancet*, 1945), in a masterly report on penicillin for early syphilis, give very interesting figures of penicillin levels in blood and urine. After a single intravenous dose of 300,000 units, penicillin is demonstrable in the blood for 6 to 7 hours after and in the urine up to 17 hours. Given intramuscularly, the same dose is detectable in the blood 7 to 11½ hours after and in the urine 17 to 23 hours.

Recently an element of doubt has been creeping in as to the absolute necessity for this maintenance of demonstrable serum levels. Lloyd Jones and Maitland observe that penicillin must be present in the blood for more than eight hours, though the amount is presumably too minute to be detected by our present laboratory methods.

Suchet (1945) quotes American observers who have shown that blood penicillin levels undetectable by bacteriological examination can still be clinically efficient. Dyar, Scholtz, and Hammond (1945) conclude that a total dose of 50,000 to 70,000 units given in 5 doses yields a cure rate of 83% and 100,000 units give 91%.

Discussion

It may now be reasonably assumed that first choice of medication in the treatment of gonorrhoea should be penicillin. It is also reasonable to assume that a patient suffering from gonorrhoea would prefer to be an out-patient than a bed. That at once excludes the use of penicillin by continuous-drip methods. To continue the argument to its logical conclusion, the patient would prefer to attend as an out-patient once daily instead of two- or three-hourly for the injections. If this method can be proved to be equally efficient the medical profession also would undoubtedly prefer it. It would effect a great saving in time and trouble, and probably encourage patients to attend much earlier and more readily.

The cure of gonorrhoea by a single injection has been claimed by the American workers Romansky, Murphy, and Rittman, who use penicillin suspended in a beeswax-peanut-oil mixture; the rationale is that absorption is delayed, with consequently a more prolonged effect. Experiment showed this to be the case. The preparation of the beeswax-peanut-oil mixture is a troublesome procedure, but the results are good, and the method appears to offer the most promising line of study. Purely from a medical point of view, the overwhelming advantage of being able to cure gonorrhoea with one injection is obvious. From the social aspect its great advantages are rapid and complete cure with no prolonged and frequent clinic attendances to interfere with work or to invite publicity. No local ill effects from the injection of the beeswax-peanut-oil mixture are demonstrable clinically; histologically, in rabbits and hamsters minimum residual findings after several months were the only signs.

Urethral Irrigation

All writers are agreed that penicillin will cure gonorrhoea without concurrent urethral irrigation, and I can confirm this. Penicillin will readily lead to the death of the gonococcus, but it will probably have no direct effect on the inflamed mucosa. It is logical, in my view, to remove any products of inflammation by urethral irrigation with any bland fluid; saline would do, but time-honoured potassium permanganate is even better. It is quite conceivable that stricture would be much more prone to develop in a urethra which had not been mechanically cleansed of the products of inflammation.

The Single-injection Method Described

In this series the duration of symptoms before penicillin treatment was instituted varied from one day to six weeks. Ten of the cases had received sulphapyridine or sulphathiazole, but had failed to respond. On admission all the cases were clinically acute, with a copious purulent urethral discharge. In every instance the diagnosis was confirmed by microscopical examination. No cultures were made; and may I forestall any criticism on this point by saying that the number of non-gonococcal cases of urethritis whose smear shows Gram-negative diplococci morphologically indistinguishable from the gonococcus is very small indeed. Muir and Ritchie (1932) say the diagnosis on microscopical grounds alone is "practically conclusive."

The preparation used was sodium penicillin in powder form dissolved in 5 ml. of pyrogen-free sterile water, but ordinary

sterile boiled or distilled water was found to be equally effective as a vehicle. The injection was made intramuscularly into the buttock. All cases showed a rapid (2-12 hours, average 8 hours) change from a purulent to a mucoid discharge, and after 24 to 48 hours no discharge of any kind was present. Six hours after the injection gonococci were absent from the discharge in all but one case; this man was negative the next day. Some writers describe a transient increase in discharge followed by a steady diminution, but my experience has been a steady lessening from the time of the injection.

The return to normal was maintained and no case showed recurrence. The average duration of attendance was 33 days, and the average number of smears (after prostatic massage) was five; all were negative microscopically, and clinically the patients remained well.

Toxic Effects

I have observed no toxic effects whatever, but several writers mention pain or discomfort of varying severity at the site of injection. This undoubtedly varies with the brand of penicillin and with the technique of injection; some preparations of penicillin seem to be much more prone to cause discomfort than others. Other reactions which are described are: venous thrombosis; I always use the intramuscular route, and this problem does not arise; an urticarial attack after the injection in a patient with an asthmatic history, but no reaction from a different brand of penicillin; an alarming collapse after 500,000 units intravenously in another; and occasionally pyrexia, headache, shivering, and nausea.

Disadvantages

The single-injection method has several demerits: (1) The danger of producing a penicillin-fast strain of the gonococcus; all the cases described were apparently cured, but this possibility must be borne in mind. (2) The default rate is much higher than with sulphonamide treatment, and it is hoped that the use of concurrent urethral irrigation will encourage men to continue with clinic attendance. (3) The very real danger of masking an early syphilis; the necessity for regular serological tests for the following twelve months must be strongly impressed on the patient.

Conclusions

The single-injection method of 200,000 units of sodium penicillin injected intramuscularly promises a rapid, simple, and trouble-free method of curing gonorrhoea; its effectiveness can only be decided upon after its use in a large number of cases under continuous supervision.

It follows that, to kill the gonococcus, (a) a demonstrable amount of penicillin in the blood need not be maintained for as long a time as has hitherto been believed, or (b) that level is needlessly high.

My thanks are due to Dr. Alexander Johnstone, medical officer of health, Greenock, for permission to publish this paper, and to the Department of Health for Scotland for making available to me a supply of penicillin.

The Servers of the Blind League started its work after the war of 1914-18 with social clubs for the blind in different parts of the country and a Braille correspondence circle. Since then it has increased its activities with the Ellen Terry National Homes for Blind Defective Children at Reigate, a home for the aged blind at Arneton House, Woking, and the Robert Spurrer Home at Ascot. This organization is now appealing for funds for a nursing home (to be opened this year) with wards for bed-ridden blind patients and a special wing for private patients, and for a new home for the aged blind. For the latter the League has in view a house in Sussex, which has the accommodation necessary to provide single and double bed-sitting rooms, as it is felt that "a room of one's own" is the desire of all old people, even the blind. This new home will also cater for blind people with limited incomes. Donations should be sent to the organizing secretary, Servers of the Blind League, 28, Manchester Street, London, W.1.

Medical Memoranda

Ulceration of a Foreign Body through the Small Intestine

The following is the report of an interesting cause of the "acute abdomen."

CASE REPORT

A married woman aged 62 was seen in the casualty department of Harrow Hospital on Aug. 31, 1945. She complained of severe lower abdominal pain for the past five hours, and also attacks of a similar nature, but lasting for only half an hour, on several occasions during the previous four days. There was no history of any gastrointestinal upset or renal symptoms. Examination showed that she was a healthy but very obese woman; temperature 97.8°; pulse 64; B.P. 150/80. The tongue was clean, but there were dulness to percussion, tenderness, and guarding over the whole of the lower abdomen. Pelvic examination was rendered inconclusive by the marked obesity. However, a provisional diagnosis of a twisted ovarian cyst was made, and the patient was admitted to the hospital for laparotomy.

The abdomen was opened through a midline subumbilical incision. The pelvic organs were examined and found to be normal. It was noted that the whole of the small intestine was slightly injected, this reaction being most pronounced in the terminal 15 in. (38 cm.) of the ileum. The whole of the small intestine was carefully examined and a thin piece of wood 2 in. (5 cm.) long, shaped like a tooth of a comb was seen to be ulcerating through the mesenteric border of the ileum 8 in. (20 cm.) from the ileo-caecal junction. Both ends of the foreign body were lying in the peritoneal cavity, the middle section being embedded in the wall of the ileum. Surrounding the "perforation" was an area of fibrinous peritonitis. The foreign body was removed by simple traction and the raw area oversutured with peritoneum. Five grammes of sulphonamide powder was put into the peritoneal cavity and the abdomen closed in layers.

Post-operative convalescence was entirely uneventful, and the patient was discharged eighteen days later.

DISCUSSION

This case is reported with the object of emphasizing the very real importance of making a careful examination of the entire gut during the course of an exploratory laparotomy. It may be added that, even after most careful questioning, the patient could at no time recall having swallowed anything in the nature of the foreign body which had been recovered from the abdomen.

I wish to thank Mr. D. K. Mulvany and the chairman of the medical staff for permission to publish this case.

K. E. E. READ, M.B., B.Chir.,
Senior House-Surgeon, Harrow Hospital.

Myiasis in the Auditory Meatus of a Newborn Infant

Although myiasis of the external auditory meatus has been reported as being not uncommon in the Tropics I can find no record of its occurrence in West Africa, and the following case appears to present features of sufficient rarity to warrant publication.

A 3para Hausa woman, aged 26 years, was delivered of the first infant of a twin pregnancy at 4.30 a.m. on Dec. 27, 1945, in "far bush." Thirty hours later she was safely delivered of the second twin in this hospital following internal version for a transverse lie. This second twin, on the fourth day of its life, was noticed to have a little fresh dried blood in its left auditory meatus. The following day the child appeared somewhat drowsy, and examination of its ear revealed a "worm" deep in the meatus. This was extracted without undue difficulty or damage to the worm, and was identified by Dr. Reid of the Research Laboratory, Accra, as the fully developed larva of the larviparous fly genus *Sarcophaga*—species uncertain but possibly *haemorrhoidalis* or *juvencula*.

It was evident from its development that the larva had been deposited on the day the child was born and probably within a few minutes of its birth. The child had been delivered in a mosquito-proof theatre and had at once been taken to a mosquito-proof nursery. Larviposition must have occurred on the short journey along an open verandah from the theatre to the nursery.

Stitt (*Tropical Diseases*, 5th ed.) writes: "A very common finding in the Tropics is that of fly larvae in the external auditory meatus where there is otitis media . . . many cases have been due to *Sarcophaga*"—that is, Stitt reports its occurrence where there has been otorrhoea. Its occurrence in a normal ear, as in this case, is believed to be very rare. The infant has suffered no permanent damage.

I am indebted to the D.M.S., Gold Coast, for permission to record this case.

Maternity Hospital,
Korle Bu, Accra.

Medical Officer, Colonial Medical Service.

Reviews

ANAESTHESIA FOR THYROID OPERATIONS

Anaesthesia in Operations for Goitre. By Stanley Rowbotham, M.D., D.A. (Pp. 104; illustrated. 12s. 6d.) Oxford: Blackwell Scientific Publications.

This is a monograph devoted to only one of the many problems the solution of which the anaesthetist must have at his finger-tips. Dr. Rowbotham, who has obviously had much experience of goitre anaesthesia, accomplishes his task admirably. The text is clear and full of practical clinical details not to be found anywhere else. Emphasis is rightly laid on the conception that the anaesthetist must be not only a good technician in the operating theatre but a good doctor at the bedside, understanding more than a little of the patient's disease. A brief but lucid account is given of the surgical anatomy, symptomatology, and treatment of the various types of goitre in so far as they are of interest to the anaesthetist; only then does the author discuss anaesthetic technique. Every conceivable difficulty likely to be met by the anaesthetist is discussed. Those to whom an endotracheal tube is anathema will find a doughty opponent in Dr. Rowbotham, who worked with Cecil Joll at the Royal Free Hospital for many years. The experienced anaesthetist should pause before disregarding the advice given by him—to use an endotracheal tube for thyroid operations. The reader is told how the thyroid patient should be dealt with before operation and how to tackle the occasional acute emergency which sometimes occurs, even with the best-regulated operation team, after the operation is over.

The book is lavishly and, what is more important, helpfully illustrated with photographs and drawings. It is in fact up to the standard which medical readers now expect from Blackwell Scientific Publications. Now that this book is available, surgeons are entitled to expect from their anaesthetists a high standard of anaesthesia for goitre operations.

AMERICAN PAEDIATRICS

Mitchell-Nelson Textbook of Pediatrics. Edited by Waldo E. Nelson, M.D. Fourth edition, revised. (50s.) London: W. B. Saunders Company.

For its fourth edition the well-known "Griffiths and Mitchell" takes on a new editor and a new format. Prof. Waldo E. Nelson successfully manages a team of nearly fifty contributors, and the result is a double-column textbook of 1,350 pages, and 519 illustrations, many in colour. This is a first-class piece of work and a single-volume reference book of a high order. The editor is an old pupil of the late Dr. Graeme Mitchell, whose death at the early age of 52 was a tragic loss to paediatrics. Prof. Nelson starts off, therefore, with the advantage of knowing what the late editor had in mind for the development of the book. The reviewer cannot tell whether or not he has successfully carried out such plans, but the result is certainly a worthy product of the Temple University School of Medicine. The various monographs are well edited to secure a unity of presentation. References appear to be adequate and not too pedantically numerous. There is a good index. The quality of paper and of illustrations raises some envy in the reviewer, who has to use, daily, books of much inferior production, even if the subject-matter is beyond reproach. The new Mitchell-Nelson textbook is sure of as good a reception in this country as that of earlier editions. It gives an excellent account of American paediatric outlook and practice at the present time.

THE PARIS MEDICAL FACULTY

La Faculté de Médecine de Paris: Ses Origines, ses Richesses Artistiques. By Pierre Valléry-Radot. (Pp. 78; illustrated. No price given.) Paris: Masson et Cie. 1944.

Dr. Valléry-Radot, who is a well-known French author, has compiled this account of the Paris Medical Faculty, including descriptions of its admirable monuments and mediaeval apparatus. He has avoided the danger of making his work too erudite and long, or too archaeological and brief.

For 150 years up till the Revolution the Faculties of Medicine (1369–1792) and Surgery (1691–1775) were entirely separate, with their own teachers and students. In the first two chapters the author traces the history of both these faculties up to the time of their fusion, and in a well-documented way shows the struggle

ment and the people. Doctors had to contend against monk "fizicians" in monasteries and barbers who were unwilling to cede their rights to surgeons. In 1769, at the instigation of Louis XV, a new School of Anatomy was instituted. It was lavishly constructed, and served its purpose well for 25 years, when another college was opened—"L'École de Santé," memorable for being the end of the long-standing separation between physicians and surgeons and their interminable disputes. This school with its big lecture halls was devoted mainly to theoretical anatomy. Ten years later the College of Practical Anatomy was founded. In it students were taught "all the dissections and operations of surgery and were shown the advantages and inconveniences of operating." Despite all these improvements, which gave the Paris Medical Faculty two sets of buildings—theoretical on one side, and practical on the other—it was decided in 1936 to start the "Hôpital des Cliniques," embodying the latest features of modern medicine. Owing to war conditions this building is not yet finished. The penultimate chapter deals with the Dupuytren Museum and its immense collection of pathological anatomy specimens; it also houses the departments of anthropology, biology, and tropical medicine.

Paris is rich in medical artistic treasures and historic monuments. These have received much attention from the author, who includes many fine illustrations in his book. Dr. Valléry-Radot is keen on his subject and has elucidated many interesting facts from the bibliography, a list of which he gives at the end of the volume.

A CARDIAC ABNORMALITY

Pre-Excitation: A Cardiac "Pre-Excitation" Phenomenon. Patho-Anatomical, and Clinical Spread Phenomenon bearing upon the Problem of Pre-Excitation (Parkinson, and White) Electrocardiogram and Paroxysmal Tachycardia. By Richard F. Öhnell. (Pp. 167; illustrated. 15s.) London: Henry Kimpton.

Dr. Öhnell's monograph describes studies of the spread of the excitation wave in the heart bearing upon the problem of the Wolff-Parkinson-White electrocardiogram. This is a very technical matter which is at present familiar only to cardiologists. Nevertheless, since the curves were first described by the above-mentioned writers in 1930 some 120 papers on the subject have appeared.

The syndrome is marked by the following characteristics. The conduction time from auricle to ventricle (P-R interval) is abnormally short. The ventricular complex which follows is abnormally prolonged and of unusual form. It resembles that of bundle branch block in some respects. These abnormal curves are not always present in any one patient, and various causes can make them disappear or reappear. The most satisfactory explanation for the curves is that there is a second conducting path to the ventricles, in addition to the bundle of His. The authors have adduced some very convincing evidence that in one case of theirs they found at necropsy a small bundle running from the left auricle to the left ventricle. This might transmit the impulse as well as the bundle of His, so that the left ventricle recorded two impulses, one a little before the other, with the result that the actual excitation time of the ventricle appeared to be prolonged. A further association of this conduction phenomenon is the frequent occurrence of paroxysmal tachycardia. It seems possible that the impulse causing these attacks circulates through the conducting channel. Normal curves may replace the abnormal on changes in posture, after thyroidectomy, and after quinidine and atropine. The abnormality has no pathological importance and is found in normal, healthy hearts.

The monograph is full but is by no means easy reading, for its disjointed style, not always clear in expression, makes assimilation difficult. The chief importance of the syndrome would so far appear to be the recognition of it as harmless, and its differentiation from the prolongations of conduction which are of pathological significance.

Notes on Books

In the abstracts which appear month by month in the *Tropical Diseases Bulletin* and the *Bulletin of Hygiene* (and in the *Bulletin of War Medicine* during the war) the Bureau of Hygiene and Tropical Diseases records the current literature on subjects coming within its fields of interest. From time to time the Bureau has been asked for information on some particular branch of medical work to be collected in the form of a monograph for the greater convenience

of persons engaged on a special problem. Such a monograph has recently been compiled for the Tsetse Fly and Trypanosomiasis Committee appointed by the Secretary of State for the Colonies, and though designed to meet a particular need it may prove useful to a wider public. *A Survey of Recent Work on Trypanosomiasis and Tsetse Flies* is therefore now published as Bureau of Hygiene and Tropical Diseases: Review Monograph No. 1, and provides a brief statement of work done, and some of the opinions expressed, by those who have worked at the different problems concerned with trypanosomiasis since 1931. The compilers are Dr. Charles Wilcocks, Dr. J. F. Corson, and Mr. R. L. Sheppard. Copies may be had from the Bureau, Keppel Street, Gower Street, W.C.1, price 7s. 6d.

Dr. JOSE MARTORELLI has expanded his thesis for the Doctorate of Medicine into a monograph entitled *Fotografia Alergologica*, published by the firm El Ateneo in Buenos Aires. It is a carefully worked out contribution, largely botanical, to the study of hay-fever in the Argentine Republic. The main part of the volume is devoted to the allergenic character of the flora of the Department of Rio Cuarto. In all there are 169 figures, mainly reproductions of photographs. An appendix by the author and his senior colleague, Dr. Roberto F. Carron, discusses the frequency of positive tests for pollinosis at the allergy centre in the National University of Cordoba.

We have received from Henry Kimpton a third and revised edition of E. V. COWDRY'S *Textbook of Histology*. The author is professor of anatomy in the School of Medicine of the Washington University, and the subtitle of the book is "Functional Significance of Cells and Inter-cellular Substances." As before, his method of presentation centres about the blood vascular system as the principal integrator, and he describes structure and function together in their natural fluid environments. The price of the book in this country is 35s.

Preparations and Appliances

RADIO AID TO HYPNO-NARCOSIS

Dr. A. OWEN-FLOOD writes:

Hypno-narcosis using an inhalant such as nitrous oxide-air gives an all-round satisfactory method for psycho-analysis. There are, however, a few difficulties in its administration which not even the strictest attention to technique can overcome. These are as follows:

(1) It is essential to have a gas-tight mask if gas-air analgesia is to be efficient.

(2) It is impossible in hypno-narcosis to attain this if the patient is to talk under its influence. Unless the mask is lifted all that emerges from its depths is a muffled gabble of groans. With the

lifting and subsequent replacement a "swinging" type of analgesia is produced where the patient comes up into a more conscious level of hypnosis, makes a response which may not be a true guide to the state of the subconscious, and again sinks into deeper hypnosis.

(3) What the radio crooner dinned into our ears some months ago—"It is not what you say, but the way you say it"—may not be quite true in psycho-analysis, but the tone and method of expression are certainly useful evidence.

(4) The necessity for the analyst to take down all that is said, which is more an annoyance than a difficulty. Being no calligraphist myself, and remembering the poor reputation in that respect of most of my colleagues, a sure method of recording the actual words would be a boon, and would earn the blessing of our hard-working secretaries.

The apparatus illustrated will, I believe, eliminate all these difficulties. It consists essentially of a small microphone fitted inside a standard thyroid mask of rubber composition. The microphone is a small crystal type, sensitive to the merest

FIG. 1

whisper. It is coupled by leads to an audio-frequency amplifier and dynamic producer. This is a neat apparatus measuring 12 in. by 8½ in., and standing 9½ in. high. A more compact and lighter apparatus is possible. This one is in its rough experimental state. It consists of three pentode valves used in a resistance-coupled circuit made to have a rising characteristic

frequency, and is specially compensated to eliminate undesirable echo which results from close proximity of the mask to the patient's mouth and the confined space in which the microphone is fitted.

Inset in the cabinet is a loud-speaker. A plug is fitted for another speaker with which it is possible to transmit the voice to a distance, such as another room. This would allow details to be noted and recorded by a confidential secretary.

FIG. 2

FIG. 3

The control panel consists of two switches which, pressed to the "on" position, light a small ruby button. This warning light shows that the apparatus is in circuit, and after a short pause for the preliminary "warming up" is ready for use. The speaker in the apparatus can be switched off and allow the remote speaker to function only, or the latter can be disconnected completely from the machine. There is also fitted a volume control, producing anything from a whisper to a roar, and a tone control, giving perfect voice reception.

The makers are now going into the question of fitting a handy recording device, details of which are not yet available. They are handicapped by the shortage of materials and labour.

To sum up: the apparatus allows a quiet state of level hypno-narcosis. The voice is heard clearly and distinctly and is capable of being amplified and transmitted to a distance. When conditions permit, a recording device can be fitted and records made of the voice. These can be played on an ordinary gramophone turn-table.

I wish to thank the directors of Messrs Stanley Cox Ltd., 11, Gerrard Street, W.1, who made the experimental model, and who are ready to supply a more efficient and portable article than the one illustrated, and Messrs. L. Lowery and R. L. H. Ewin, of the research department of the above firm, for their untiring work in the production of the sensitive instrument. I am grateful for the encouragement of Dr. Marion Greaves, West End Hospital for Nervous Diseases, for making the first trial, and reporting and suggesting improvements in the apparatus; and to Dr. C. H. Rogerson, Cassel Hospital, Stoke-on-Trent, who has promised to make a further trial for me.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 2 1946

ARE THE PEOPLE MORE HEALTHY?

As a result of the propaganda during the past six years Britain has become more health-conscious, and the reactions of a Press with a limited supply of paper show that health now has a news value. The maintenance of as high a standard of well-being as possible among the civilian population was essential for the successful waging of war, and the many statements on improved or better general health among the public were accepted loyally and without undue criticism of their obvious propaganda nature. The assessment of health for comparative purposes during the war was difficult, because there was no standard available and accurate information was lacking. The death rate gives a broad indication of the nation's health, but mortality is not very sensitive to relatively small changes in environmental conditions, and even large adverse deviations in nutrition do not immediately affect the general death rate. Tuberculosis, however, reacts fairly quickly to adverse conditions, and it soon became apparent that, as in 1914-18, with the outbreak of war there had been a reversal of the favourable pre-war trend of tuberculosis mortality. One of the most disquieting features of the early war rise was the increased mortality of children from tuberculous meningitis. Infant and child mortality are sensitive to social, economic, and environmental conditions, and for comparative purposes these rates generally reflect the condition of the general population fairly accurately. Priority allowances of food for children naturally invalidated any attempt to reach conclusions concerning the adult population from the children's experience. And only an approximate and indirect estimation of the nation's health is given by the trend of the notifiable diseases.

In January, 1944, an attempt was therefore made to get a direct estimation of the sickness experience of the nation. The field workers of the organization known as the War-time Social Survey interviewed a random sample of the civilian population between the ages of 16 and 64 in all parts of the country. These surveys were repeated at intervals, and later the investigation was extended to cover ages over 65, although results for the latter age group have not yet been published. The number of persons interviewed in any one survey varied from 2,000 to 2,500. The information sought was of the illnesses experienced during the preceding three months. Generalizations from the sample to the

whole population may be affected by the smallness of the sample—only 1 in 20,000—the ability to remember the details of any sickness experienced during the preceding three months, and the fact that many of the complaints were self-diagnosed. As different areas were covered in each survey the continuity of the trends, particularly those of influenza and colds, may be affected to some extent by chance, because these diseases do not always have the same time of maximum incidence even in adjacent areas. Brief summaries of the findings of these health surveys have been published periodically in the *Monthly Bulletin* of the Ministry of Health and the Emergency Public Health Laboratory Service. The sicknesses have been grouped into four categories: serious—producing incapacity for work for four weeks or more or involving risk of death; moderate or mild—sickness incapacitating for three days or more; minor—ailments which do not incapacitate for as long as three days at a time; symptomatic—ill defined without a definite diagnosis.

During the period October, 1943, to May, 1945, about two-thirds of the persons aged 16-64 recorded at least one new illness or the recurrence of an old one starting during the period of three months preceding the interview. The monthly incidence of serious illness has a pronounced winter rise and a summer minimum, the trend being similar to that of mortality. The proportion of persons recording a serious illness has decreased during the period: in the winter of 1943-4 it was 2%, and in the following winter the percentage was only slightly over half this value. The proportion having a moderate or mild illness has declined even more—from over 15% in the winter of 1943-4 to almost a third of this rate in the winter of 1944-5. The monthly trend of minor ailments does not show any definite progression, and high values have been recorded in winter and summer; the percentage monthly incidence over the whole period varied from 13 to 28. Sickness with ill-defined symptoms follows a similar trend to that of minor ailments but at a much lower level, the monthly percentages ranging from 3 to 8. There are not the same large differences in the average number of days of incapacity as there are in the attack rates. The numbers of days lost by serious illness per 100 persons exposed to risk were 79 and 64 for November and December, 1943, and 64 and 55 for November and December, 1944. Days lost from moderate or mild illnesses were 110, 117, 78 per 100 persons per month during November, 1943, to January, 1944, compared with 54, 57, 62 for the same months in the following year. The monthly average for minor ailments ranged from 5 to 22 during the period. There was little alteration in the length of serious illness; the duration per month fluctuated from 23 to 48 days.

Moderate or mild sickness has become increasingly important as a cause of lost time: from November, 1944, to March, 1945, the average length of illness varied from 10.4 to 12.9 days, while the range for the preceding months was 5.3 to 9.3. The number of days of illness for minor ailments varied from 0.2 to 1.4. Influenza and colds form the most important cause of sickness; the average monthly

incidence per 100 exposed to risk during the winter of 1943-4 was 21.6 for males and 22.2 for females, and in the following winter the rates were 17.8 and 18.4 respectively. Rheumatism appears to be slightly more prevalent among women than among men, and this complaint was recorded more frequently in the summer than in the winter—during the summer of 1944 the average monthly incidence was 4.5% for males and 6.0% for females. It must be repeated here that the "rheumatism" was often self-diagnosed. Women made more frequent mention of nervous ailments than men: the number said to be affected by "nerves," at each interview, ranged from 1.2 to 3.5% among the males and from 2.7 to 8.3% among the females. The incidence of debility and certain nervous symptoms was 1.5 to 4.1 for men and 2.6 to 6.4 for women. The percentage suffering from neuritis, cause unknown, varied from 0.1 to 1.0 for males and from 1.0 to 1.7 for females. Functional digestive disorders appear to have increased slightly by the end of the period, but there was no obvious sex differentiation—in three of the six interviews the female attack rate exceeded the male rate. The incapacitating effect of these diseases differed between the sexes. "Nerves" caused 1% or more of the women to be laid up for one day or more in three months on four out of the six occasions, while the percentage of "nervous" males was only 0.6 to 0.8 during five of the periods. For the other three groups of complaints combined the males had more incapacitating sickness than the females: the percentage of males laid up for a day or more in three months varied from 0.6 to 2.2, while for females the rates were from 0.4 to 1.0.

For the period November, 1943, to January, 1944, an analysis was made of the number of visits to doctors. The average visits per person in the three months, whether ill or not ill during the period, were 1.04 for males and 0.88 for females to the doctor's house, and visits by the doctor to the patient's home were 0.45 for males and 0.56 for females. Attendances at hospital out-patient departments were 0.14 for males and 0.10 for females, and at clinics, place of work, etc., 0.09 for males and 0.12 for females. Expressed on a daily basis, the average visits per day for each 1,000 persons was 18.4, of which 5.7 were at the patient's home and 10.2 at the doctor's house. These values relate only to persons aged 16-64; they would be considerably higher if ages under 16 and age 65 and upwards were included.

There are two obvious weaknesses in this type of survey. The first is the smallness of the sample, and the second is that reliance has to be placed on the patient's description and diagnosis of his illness—or rather on his interpretation of the doctor's diagnosis. And the second weakness must be increased by the difficulty of finding suitable persons to conduct the survey. If in peacetime far larger samples of the population could be investigated, and if people get used to the idea of social medicine conducted in this way, then the survey started during the war should bring in more and more useful returns, and enable those in charge of, and working in, the Health Service to get a much more accurate measure of the health of the people than has been possible in the past. What we want is more information and less propaganda.

SEX HORMONES

During the war a number of books on endocrinology appeared in the U.S.A. As might be expected, some were good and some were bad, but it may not be too severe to say that, while the good were only fairly good, the bad were very bad. The worst were those which sought to "jump the band waggon" by implying a special wartime importance for endocrinology. In reality endocrinology appears to have been one of the few fields of research which yielded little or nothing for the war effort. In this country, and probably in Europe, endocrinological publication was much reduced during the war. It is likely, however, that the lull is about to end. In the occupied countries of Western Europe many scientists, debarred from their laboratories or having exhausted their reagents and eaten their experimental animals, devoted themselves to writing, and several books on endocrinological subjects have appeared or are on the way from France and Holland. It will be interesting to see what is forthcoming in this country, and how the very complex subject of endocrinology is tackled in post-war publications. One of the most difficult branches is the endocrinology of reproduction, the theme of a recently published book by Mr. Harold Burrows.¹ The subject has expanded enormously in little more than a decade, and a vast mass of material has to be dealt with by reviewers. The difficulties of presentation are obvious. How should the material be stratified—according to hormones, organs, animals, or phases of the reproductive cycle? How much fundamental biology should be included? Should the aim be to include every reference, catalogue fashion, or attempt a general description in broad terms? Should one illustrate profusely or not at all? Those who are primarily biologists prefer to approach the subject from the point of view of the integration of bodily function. They ask, for instance, what chain of events results in a rabbit ovulating after mating and only then? Or, why does the mammary gland burst into secretion after parturition? By contrast, those to whom a hormone is something in a bottle on a shelf naturally have a different approach. They ask—if an extract of men's urine grows a comb on a capon, what will it do to a pregnant rat? Or, if progesterone stimulates the ovipositor of a fish, will it relieve dysmenorrhoea? It is a remarkable testimony to the size of the endocrinological target that such grapeshot research has sometimes scored a bull.

Mr. Burrows takes a firm line with the question of literary logistics. He arranges his material according to the various hormones, and under these headings mainly according to properties and to the organ or tissue acted on. This arrangement facilitates reference, but it produces some odd results. For instance, the first three pages of the book are largely taken up by a description of the effects of proteolytic enzymes on gonadotrophins—a rather prominent position for such a subject. References to the literature are voluminous rather than selective, and will delight readers of the kind who turn first to the index of authors. There are no half-tone illustrations and no diagrams other

¹ *Biological Actions of Sex Hormones*, by Harold Burrows, C.B.E., Ph.D., F.R.C.S. Cambridge University Press. 42s.

than chemical formulae. The result is a book which is a mine of information about the effects of reproductive hormones and related substances when administered to the animal, and a book which cannot fail to be much used for reference purposes. In some ways, however, it is unsatisfying. To many workers the action of exogenous hormones is of interest mainly in so far as it throws light on the build-up of the normal animal. As it concerns the hormones associated with reproduction, this approach demands a considerable knowledge of the changes occurring in the normal reproductive processes. Mr. Burrows, however, gives little attention to the biological background of the reactions he describes, and the occurrence of oestrogen in the ovarian follicle is catalogued in the same non-committal way as its alleged presence in asphalt. Similarly, actions of the gonadal hormone which in our present state of knowledge seem trivial and incidental are not sharply differentiated from functions essential for reproduction.

In general one wishes the author had taken more trouble to indicate the probable relevance of the observations he records, even if this had meant more selection of his material. Interpretation is, of course, always dangerous, and he may well have been dismayed by the incredible miscellany of observations recorded in the literature and by the notorious propensity of reproductive endocrinology to confound its interpreters. Nevertheless, while all things are possible, some things are more likely than others even in this phantasmagorical field, and more expression of opinion on the part of the author would have enlivened the book. Its two-page glossary contains an excellent summary of the definitions of international units of sex hormones, but is otherwise so selective as to be of little value; and there is a list of proprietary hormone preparations, useful but perhaps somewhat out of place in a scientific treatise. Mr. Burrows's book is one which all those interested in the subject should have available for reference, and one must congratulate the author who, after a busy life as a surgeon, not only has made important contributions to research but has accomplished successfully a literary undertaking of this magnitude.

SINUS BAROTRAUMA AND AEROSINUSITIS

The war of 1939-45 has created conditions for high-altitude flying. It gave the man on top great tactical advantage. Thin air encountered at such altitudes increases air speed for any given power output and renders flying comfortable under adverse weather conditions. Until high altitudes became common few people were ever subjected to great changes in barometric pressure. The effects of these pressure variations upon closed cavities containing gas and air were observed in the syndrome of sinus barotrauma or aerosinusitis, characterized by congestion and acute or chronic inflammation of the sinus membranes. Temporary or permanent changes in the sinus mucous membrane, such as mucosal or submucosal haemorrhage, may result, depending on the amount of barotrauma. Pain over one or more sinuses, usually the frontal, often described as a "sting over the eye" or "a blow by a crowbar," is commonly the onset of the syndrome. This severe form is associated at times with stripping of the mucous membrane or submucosal haemorrhage, whilst in

less dramatic instances the pain develops slowly on descent or after return to ground level. An explanation advanced by McGibbon¹ is that during ascent the relatively increasing pressure within the sinus cavity causes an ischaemia of the mucosa. On descent, with a relatively decreasing pressure of the sinus air, engorgement of the mucosal capillaries results in oedema, effusion, and haemorrhage. In the absence of any previous sinusitis x-ray evidence² of opacity or thickened lining membrane is suggestive of barotrauma. In a large number of patients, however, especially those in whom the only abnormal signs are radiological, it is almost impossible to differentiate cause from effects of barotraumatic changes.

A submucous haematoma of the frontal sinus was first described by Herman³ and later by P. A. Campbell.⁴ In a case of recurrent frontal sinus barotrauma an apparent "polyp" removed by McGibbon was found to be a haematoma encapsulated in a densely collagenous fibrous tissue and undergoing organization. There was no inflammatory infiltration to suggest infection. Experimentally the picture has been reproduced by P. A. Campbell and his co-workers in a dog decompressed from 28,000 ft. (8,500 m.) after tight packing of the naso-frontal duct. Examination disclosed a large haematoma extending upward from the internal orifice of the duct. Multiple small mucosal haemorrhages were found to arise between the epithelium and the periosteum in lightly vascularized areas of the mucosa. The mucosa of the unobstructed sinus was normal. Biopsy sections of antral mucosa have been examined in a few cases of recurrent sinus barotrauma by C. Campbell⁵ in a series of cases observed in the R.A.F. Subacute or chronic inflammatory changes, marked oedema, congestion, small mucous or submucous haemorrhages, plasma cells, polymorph and lymphocytic infiltration of the mucosa, and a moderate degree of fibroblastic hyperplasia were observed. But exactly similar changes may be found in the mucosa in subacute and chronic infective antritis in which there has been no question of sinus barotrauma, so that in these few barotraumatic cases the histological appearances are probably those of a complicating infective antritis. Age, amount of flying experience, nature of aircrew duties, and type of aircraft flown are not predisposing factors, and the aetiology of the syndrome is that of many contributory factors. These may be developmental, traumatic, allergic, infective, neoplastic, or mixed. It is difficult to assess the incidence. Figures are unreliable, as in many patients the contributory factor clinically overshadows the effects of barotrauma. P. A. Campbell gives an incidence of otitic barotrauma as 1 in 20. In a series of cases observed in the R.A.F. and reported by McGibbon the relationship was approximately 1 case of sinus barotrauma to 4 of acute otitic barotrauma. In a series of experimental cases subjected to decompression the ratio was 1 to 5. It was further noted that the results of infection of the upper respiratory tract are the most frequent contributory factors. At the same time it must be stressed that many individuals suffering from acute and chronic upper respiratory infections, established infective sinusitis, and polyposis fly without experiencing any ill effect.

The diagnosis of sinus barotrauma is founded largely on the patient's complaint of pain, and the syndrome lends itself to hysterical mimicry and perpetuation as a means of escape from duty. Observations extending over a long period and based on the examination of a large number of cases have led to this conclusion. The differentiation of true sinus barotrauma from neuropsychiatric symptoms

¹ J. Laryngol. Otol., Nov., 1944, 59.

⁵ J. Laryngol. Otol., Nov., 1944, 59.

which simulate the syndrome is aided by an experienced examiner's observations of the patient's reactions during a standard decompression test.

Prophylaxis can be summed up briefly. Flying should be avoided by anyone suffering from an acute or chronic upper respiratory infection. Treatment is expectant, and any manifest contributory factor should be corrected. Relief of symptoms occurring during descent from height can be obtained by re-ascent, if in an aircraft, or decompression in a chamber, followed by very gradual loss of height.

ISLET-CELL TUMOURS

The literature on tumours of the islets of Langerhans and the symptoms with which they are associated is piling up. An admirable short historical survey and report of a case successfully treated by surgery have recently been given by Stanley R. Maxeiner and Harry E. Bundy.¹ These tumours were first recognized as long ago as 1902, but, probably because the first twenty reported were asymptomatic, were thought for many years to be of academic interest only. The discovery of insulin and insulin shock led soon to the realization that islet-cell growths may often cause symptoms due to hypoglycaemia: Whipple² has collected 149 cases of this type.

According to their size and malignancy the tumours may be wholly without effect on function; may cause minor disturbances amenable to medical treatment by glucose and careful regime of life; may require surgical treatment; may cause fatal uncontrollable hypoglycaemia—for example, when metastases form in the liver. The diagnostic criteria are, according to Whipple, symptoms of insulin shock coming on in fasting or fatigued persons; a blood-sugar level of 50 mg. or less per 100 ml.; and prompt relief of symptoms by glucose. Maxeiner and Bundy, however, stress that the diagnosis is difficult in many cases, and, as in hyperthyroidism, this must clearly be so in early and mild phases of the disorder. Glucose-tolerance tests are unreliable, and administration of alloxan is not an effective diagnostic measure. Other causes of hypoglycaemia must be excluded. Usually the tumours are single, but in about 10% of cases two or more have been found. In Maxeiner and Bundy's case eight inactive tumours and one active were found. Whether a condition analogous to primary thyrotoxicosis affects the islet tissue, as suggested by Frantz,³ is uncertain. About two-thirds of all tumours are apparently benign, one-tenth certainly malignant, and the remainder doubtfully so. They are commonly found in the tail and body of the gland. (A paper by Louis P. Good⁴ on the histopathology of the tumours suggests that the tumour capsule is really compressed duct wall of the pancreas, the presence or absence of a capsule depending on the site of origin of the growth.)

In describing the surgical approach Maxeiner and Bundy emphasize that it may be very difficult to identify the tumour (or tumours) at operation; and several cases have been reported in which two or more operations were performed before a cure was obtained. When no growth can be found they advocate resection of the body and tail of the pancreas as being the most usual site of the tumours; the alternative is to close the wound and wait until such time as the tumour is big enough to be recognized at a subsequent laparotomy. Both courses have obvious disadvantages.

By reason of the nervous manifestations which they often cause the early recognition of islet-cell tumours is

of obvious importance. Dizziness, nausea, pallor, and sweating may at first be mistaken for part of a psychoneurosis or even alcoholism; convulsions, clonic contractions, and coma may, as in the case described by Maxeiner and Bundy, lead to a diagnosis of epilepsy; while maniacal seizures may produce serious consequences for which the patient cannot be held responsible. Citing another case, M. S.-M. Rayner, C. H. Rogerson, and J. G. Jones⁵ point out that a diagnosis of hysterical or convulsive fits should never be made until hypoglycaemia has been excluded. Minor degrees of insulinogenic hypoglycaemia may not be uncommon, even when a firm diagnosis cannot be made, and it would seem justifiable to give glucose a clinical trial in any case of recurrent nervous manifestations of the type described, especially if they occur in fasting conditions (e.g., early morning) or after physical exertion.

THE OBLIGATION OF THE PHYSIOTHERAPIST

As a result of the war the science and practice of physiotherapy have gained wide publicity, and the chartered physiotherapist is recognized as an essential member of the rehabilitation team. Nevertheless, far too little is still known both of the standard of training and of ethical conduct required of physiotherapists. A body for the training, examination, and registration of physiotherapists has been in existence since 1894, the date of the foundation of the I.S.T.M.. A Royal Charter was granted to that Society in 1920 when it took the name of the Chartered Society of Massage and Medical Gymnastics, and in 1943 it became known as the Chartered Society of Physiotherapy, thus denoting the increasing scope of a physiotherapist. Over many years the standard of training laid down by the Chartered Society has been progressively raised, and the length of the course has been increased from a few months in 1894 to the present length of 2½ years. When the new curriculum is introduced the training will extend over 3 years.

From the earliest days the Chartered Society has insisted on a strict ethical code for its members. Before being admitted to the Register a chartered physiotherapist must sign an undertaking "not to undertake any case except under the direction of a registered medical practitioner." Attention is called to this by-law in a letter published in our correspondence columns from Dr. W. S. C. Copeman, Chairman of the Council of the Chartered Society of Physiotherapy. This ethical by-law affects not only the chartered physiotherapist but also the patient and the medical practitioner. It safeguards the patient against loss of time and money and the consequences of unsuitable treatment, while the doctor knows that he will have the loyal co-operation of the physiotherapist and highly skilled treatment for his patient.

Dr. R. D. Lawrence will deliver the Oliver-Sharpey Lectures before the Royal College of Physicians of London on Tuesday, March 19, and Thursday, March 21, at 5 p.m. at the College, Pall Mall East. His subject is "A Case of Lipodystrophy and Hepatomegaly with Diabetes, Lipaemia, and other Strange Metabolic Disturbances suggesting a New Aspect of Insulin Action."

Following the death of Sir Comyns Berkeley, the Central Midwives Board has elected Mr. Arnold Walker as chairman and Mr. J. P. Hedley as vice-chairman for the rest of the

TRAVELLER'S OEDEMA

BY

K. ZACOPOULOS, M.D.

Chief M.O. of the Greek Sacred Regiment (Raiding Forces)

In March, 1944, forty Greek officers, including myself, succeeded in escaping to Smyrna, and from there we took a train to Aleppo, Syria. The journey was most uncomfortable as it lasted four days and we were very crowded. The younger ones among us took a little exercise, pacing up and down the corridor and station platforms, but others remained almost motionless throughout the journey. Before we reached Aleppo I was sent for to look at an officer whose feet were swollen. A second case soon appeared with the same symptoms, then a third, and a fourth, until eventually an inspection of all my fellow travellers revealed that eight of them had oedema of the ankles.

A month later another party of Greek officers reached Smyrna, and among them was Dr. Hinaris. During their journey from Smyrna to Aleppo they had had to stand for the best part of three days. Extensive oedema had appeared in the lower extremities of every member of this group towards the end of the second day of the journey.

The eight cases I attended presented oedema of both lower extremities localized to the ankle and lower third of the leg, without further signs of inflammation or of trauma. The ankles felt slightly painful and there was also a sensation of painful weight in the feet. The symmetrical oedema was not marked and hardly extended beyond the lower third of the leg. The extremity of the foot inside the shoe was not involved. No sign of lymphangitis was present, and all the ankle-joints appeared unaffected apart from the oedema and slight subjective pain during movements. We found no rise of temperature or alteration in the general condition in any of the patients. As a cardiologist I examined their circulatory systems with care and could find no abnormality.

Dr. Hinaris's cases were very similar except that the oedema was more severe and extended in some cases to one-half of the leg, and in the more severe cases to the lower third of the thigh. All our patients wore civilian shoes, in which they had escaped from Greece and travelled through Turkey, Syria, and Palestine, until they reached Egypt.

Diagnosis

The clinical appearance of these cases excluded right from the start all the conditions usually accompanied by oedema of the lower extremities. Wounds were completely absent. There was no evidence of inflammation, or of phlebitis, or of lymphangitis and lymphadenitis. There was nothing to suggest urticaria, or any trophic or deficiency oedema. None of these men had suffered from excessive malnutrition, and during our stay in Smyrna we were far from being undernourished.

It was not a cardiac oedema because careful examination of the cardiovascular system revealed no abnormality; furthermore, all our patients were regular officers who had been considered fit for military service. It was not a renal oedema because none of our patients had pyrexia, renal pain, oliguria, oedema of the eyelids, or any other symptom of nephritis.

Thus, excluding the above, we were driven to the following mechanical explanation, which we think is quite adequate.

Pathogenesis

The patients of the first group, as well as those of the second, moved very little or not at all during the journey, which is the main cause of the appearance of the oedema. The first group sat continuously with their legs suspended. The second group had to stand for hours, not doing any of the normal movements which are essential if oedema of the lower extremities is to be avoided. In this manner they unconsciously placed a mechanical strain on the venous circulation.

Movements of the limb muscles assist the venous circulation by pressing the blood from the capillaries. My cases were men in whom, apart from the immobility, the sitting position with legs hanging down had further impeded the venous return because of the bending of the knees and the pressure in the popliteal space. In the cases reported by Dr. Hinaris the

patients had been standing for long hours without movement, and this caused a more extensive oedema. In our opinion the mechanics of the condition are as follows:

The absence or reduction to the minimum of movements of the legs (voluntary or involuntary) practically stopped those contractions of the muscles which normally aid the flow of blood from the capillaries and small veins. These began to enlarge in order to receive, in addition to the existing stagnant venous blood, the new blood which was continuously moving from the arterioles through the capillaries to the small veins. Thus in the absence of the essential muscular movements a state of comparative venous stasis ensued. This factor was even more marked in the lowest venules because of the greater hydrostatic pressure of the column of venous blood. Thus the oedema began, and for as long as the lower extremities remained inactive the oedema increased.

In the first group of patients I advised movements, active and passive, especially walking, and slight massage of the oedematous area. All my patients recovered completely, and when we detrained at Aleppo none of them had oedema. In the second group of patients, too, recovery was automatic within a few days of reaching Aleppo and being able to move about freely inside the refugee camp.

Conclusions

(1) There is a form of oedema caused by inactivity to which travellers by sea, rail, or road are subject. "Deck ankles," described in para 150 of *A.M.D. Bulletin* No. 21 of March, 1943, appears to be the same condition. We consider it advisable to call this "traveller's oedema," as only this term covers all the cases that may appear. We prefer the term to two others which could be suggested: "inactivity oedema" and "orthostatic oedema." The first lays stress on the lack of movement but not on the vertical position of the lower extremities. Also we must not overlook the fact that inactivity alone in many cases does not cause oedema. The second term lays emphasis on the standing position—a most important factor, as was observed in the second group of patients; but standing without inactivity will not cause oedema of the ankles in healthy individuals. Even patients with varicose veins will not develop oedema if the heart is normal and their lower extremities are active.

(2) Traveller's oedema is caused purely mechanically in cases in which there is a great diminution, or complete absence, of muscular movements of the extremities in persons who are sitting or standing for prolonged periods.

(3) Treatment is simple. Repeated active or passive movements of the lower extremities must be started immediately. Tepid bathing of the feet is advisable, with simultaneous massage and passive movements of the toes, ankles, and calves. An elastic stocking might be tried in those few cases which do not respond promptly to massage and tepid baths.

(4) Prophylaxis is obvious. Travellers must be warned against complete inactivity, and whenever possible must avoid standing up during long journeys.

SOUTH AFRICAN MEDICAL CONGRESS

For the first time since 1919 the Medical Association of South Africa will this year hold its annual scientific meeting and medical congress. The meetings will take place in Durban from Oct. 7 to 12, 1946.

The organizing secretary, Dr. C. M. Murray, Medical House, 35, Wall Street, Capetown, invites members of the British Medical Association from Great Britain to attend the scientific meeting and to take part in its proceedings either by reading papers or in some other way. He suggests that the congress will provide an excellent opportunity for renewing and cementing the friendship between medical colleagues in South Africa and Great Britain.

The Council of the B.M.A. received the invitation with pleasure at its meeting on Jan. 30, and expresses the hope that some members could make it convenient to attend the congress and represent the Association. The Secretary will be glad to hear from any member who contemplates visiting South Africa.

L.C.C. HOSPITAL SERVICE

LARGE FUTURE DEVELOPMENTS

Wide-ranging proposals for the post-war restoration and development of its general and special hospital service were laid before the London County Council by its Hospitals and Medical Services Committee on Feb. 19. The most urgent need is the repair of war damage; of the Council's 76 hospitals, 73 have been damaged to a greater or less degree, and the cost of repairs is estimated at £2,600,000. The proposals are divided into short-term (the next five years) and long-term.

Short-term: Provision of more special units for certain types of medical and surgical treatment; improvement in facilities for treatment of tuberculosis; restoration of maternity accommodation to pre-war basis; extension of appointments system for out-patients; improvements in arrangements for visiting of patients; improvement of hospital catering; permission for medical and nursing staff to live out; establishment of medical, nursing, and domestic staff committees in each hospital.

Long-term: Provision of new hospitals in Tooting and Crystal Palace areas; acquisition of additional land for hospital expansion; provision of new maternity blocks; provision of 20 new out-patient departments; subdivision of wards to secure greater privacy; provision of special fracture units at general hospitals; provision of additional beds for tuberculous patients.

At a Press conference Mr. A. REGINALD STAMP, chairman of the committee, said that it was thought that London might be divided into some 21 districts, each of which would be served by a general hospital dealing with acute cases, with other hospitals in the district related to it, and supplying in each district what is considered in the medical profession to be a complete medical service. In 11 of these districts the main hospital might be a Council hospital, and in the others a voluntary teaching hospital. Mr. Stamp emphasized the great amount of teaching material in the Council's hospitals, and said that he hoped that his committee would be empowered to negotiate with existing teaching hospitals with a view to making certain Council hospitals available for teaching. There was good will on both sides, and the L.C.C. hoped as equal partners with the voluntary teaching hospitals to make an essential contribution to medical education.

Medical Staff Committees

The complexity of hospital organization and the increasing use made of the services of specialists have seemed to the committee to afford strong arguments for the introduction into the Council's hospitals of medical staff committees, corresponding to the medical committees in voluntary hospitals. The function of these committees would be to advise on the best use of accommodation, care of patients, improvements in staffing, and provision of equipment. If the medical superintendent agreed with such a committee's recommendations, these, within limits, could be acted on forthwith, or, when necessary, transmitted by the medical superintendent to the county medical officer; when the medical superintendent disagreed they would be transmitted by him to a higher level with his independent observations.

Concerning medical superintendents the report of the Hospitals and Medical Services Committee goes on to say:

"The clinical responsibility of medical superintendents for patients has been the subject of criticism, though some of it is not well founded. The trend of our administration, however, has been to place clinical responsibility upon the specialist in charge of the medical, surgical, or maternity and gynaecological units in which a patient is treated, and we are of opinion that this trend should continue."

Responsibility for treatment might be allocated as follows:

(1) whole-time specialists in charge of beds should be completely responsible for the treatment of the patients occupying those beds; (2) part-time consultants should, in appropriate circumstances, be similarly responsible (involving a revision of the terms on which part-time consultants are now remunerated); (3) the medical superintendent should retain responsibility for seeing that every patient is under the care of the appropriate medical officer, and for the treatment of all patients not in the care of a consultant.

"The medical superintendent should, however, remain responsible for matters of general administration and discipline, and after suit-

able consultation with the clinicians, for the allocation of beds. He should also remain responsible for the co-ordination of all services and departments, for preventing the spread of infection, and for ensuring that the instructions of the hospital committee are carried out."

It is anticipated that at least 100 additional whole-time medical officers of the registrar and houseman grades will be needed. An increased number of consultants and specialists will also be necessary, although no estimate of the number can yet be made. The number of whole-time specialists will need to be increased, and it will be desirable for a specialist to serve a group of hospitals.

Special Units

Special units for certain types of medical and surgical treatment will be situated at hospitals suitable for postgraduate training. Hammersmith Hospital (north of the river) and Lambeth Hospital (south) suggest themselves. Fracture units will probably be needed in most of the Council's "district" hospitals. Four rehabilitation centres are forecast, as well as two units for plastic surgery, one for major neurosurgery, one for major thoracic surgery, and six radiotherapy centres.

Health centres under the National Health Service scheme might adjoin Council hospitals wherever suitable accommodation can be found. The Council at present has maternity units in thirteen of its general hospitals; additional units can be opened at three others as soon as staff is available, and at two more when repair of war damage is effected. It is proposed that each district hospital should have not fewer than 50 maternity beds; also that 5,000 beds should be allocated in London for the chronic sick.

"The most urgent need, clearly, is for the repair of war damage, but progress with this work will be dependent upon the availability of labour and materials. Other problems may wear a different complexion when the Government's National Health Service proposals are known."

Reports of Societies

PENICILLIN IN TREATMENT OF SYPHILIS

At the meeting of the Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine on Feb. 12, with Dr. E. N. ALLOTT presiding, a discussion was held on "Penicillin in the Treatment of Syphilis."

Lieut.-Col. JAMES MARSHALL, before speaking of observations first in early and then in late syphilis, said that it needed at least five years to assess the value of any method of treating early syphilis, and therefore the dosage and treatment schedules recently employed for penicillin had of necessity been experimental. The experiments had, however, been on a large scale and allowed of certain conclusions and assumptions.

The treatment of early syphilis had so far been carried out mainly by multiple intramuscular injections using aqueous solutions of penicillin. With this method, almost independently of the total dosage used, *Sp. pallida* disappeared from surface lesions in about 12 hours, lesions healed quite rapidly, and positive serological reactions tended to reverse towards negative. Very large numbers of cases had been treated in the Allied armies by 2,400,000 units penicillin for seven and a half days. The speaker's own experience in a small series of 67 cases was that 10 could be classified as treatment failures at the end of six months' follow-up. A recent check at the central syphilis register at the War Office showed that in 270 cases of early syphilis treated with 2,400,000 units penicillin and followed up for six months the failure rate was 8%. At the same time a check was made on the same number of cases treated by the "20-day" arsenoxide and bismuth method, and the failure rate was only 2%.

In planning a more satisfactory method of treatment he was guided by an American observation that there was probably a synergistic action between penicillin and arsenoxide. A scheme was evolved which, after certain modifications, now consisted in giving 2,400,000 units penicillin in seven and a half days and 10 daily injections of 0.09 g. neohalarsine or 0.06 g. mapharside. Any arsenical toxic effects were rare; if they did occur arsenical treatment was stopped and the total dose of penicillin was

increased to 4,000,000 units (100 injections of 40,000 units). So far 360 cases had been treated—240 by this method and 120 by an earlier modification consisting of the same amount of penicillin and 14 daily injections of the arsenic compound. Only about one-third of this number had been so far successfully followed up for four to six months after completion of treatment, and so far there had been three cases of mucocutaneous relapse, and one case of possible and another of indubitable reinfection. There had been no case of serological relapse.

The results suggested that combined therapy with penicillin and arsenoxide, although not attaining complete efficiency, was an improvement on treatment by means of penicillin alone. Combined therapy, judging by early results, was probably in the same order of effectiveness as the "20-day" arsenoxide and bismuth treatment, and, if carried out in good circumstances, was almost without danger. For patients who had relapses after treatment with penicillin alone he now used 4,000,000 units penicillin and daily injections of 0.09 g. neohalarsine or 0.06 g. mapharside for ten days. The routine treatment in Army hospitals now consisted either of 2,400,000 units penicillin with ten daily injections of arsenoxide or of 4,000,000 units penicillin alone. One thousand cases were to be treated by each of these methods, and the results of a follow-up of such numbers should yield information of some value.

Turning to late syphilis, Col. Marshall said that osseocutaneous late syphilis of the acquired or congenital type reacted rapidly to penicillin in most cases. He had had good clinical results with gummata of the testicles. Interstitial keratitis reacted equivocally to penicillin as it did to other remedies. Penicillin given by parenteral injection in standard doses did not penetrate to the cerebrospinal fluid in demonstrable quantity, but, notwithstanding this, clinical effects were manifested. Clinical improvement had been reported in varying proportions of cases at all stages and in all types of neurosyphilis. His own observations in a small number of cases of neurosyphilis confirmed those of others that the larger the dose the better the result. He had treated neurosyphilis with two courses of penicillin, each of 2,400,000 units, at a week's interval, and had had good results. In the treatment of late syphilis of all types he now began with a course of 4,000,000 units penicillin in one hundred injections of 40,000 units extending over twelve and a half days. This might be varied a little at the start by a reduction in individual doses if therapeutic shock was to be feared. After this he gave a treatment of consolidation with bismuth or with bismuth and an arsenical, depending on the type of case and lasting at least six months.

In conclusion he said that they all agreed that some comparatively rapid method of treatment was necessary to combat the lack of enthusiasm of the patient for repeated visits to hospital. Whether this could be found in penicillin alone in single or repeated courses or in some method of combined therapy was a problem which, he feared, would not be settled for some time to come.

Dr. F. R. SELBIE who had advised Col. Marshall on the scheme for combined treatment with penicillin and arsenoxide, and to whose co-operation Col. Marshall had paid tribute, followed with some description of the experiments which had been undertaken with a view to the combination of these two therapies. The experiments had shown, he said, that penicillin had an immediate and dramatic effect which was quite comparable with that produced by means of arsenical drugs. They pointed to the conclusion, however, that penicillin ought to be supplemented by some other form of treatment such as arsenical drugs and bismuth. He thought that the least one ought to give was about two-thirds or one-half of the usual dose of the arsenical when combined with penicillin.

Proportion of Treatment Failures

Dr. A. J. KING said that penicillin was introduced as a routine treatment for early syphilis in the United States Army in June, 1944, and in the British Army in October, 1944. The remedy was untried, and to use it as a routine under the conditions then prevailing was something of a gamble. Whether the risk was justified awaited the test of time, but the immediate success of so short and safe a treatment exceeded the expectations of all but the most sanguine. At the same time the conditions were laid down for a large and important experiment in which many hundreds of patients were treated with standard doses of a new

remedy, while the facilities for following up were such as would never be available in civil life. His own observation of the proportion of treatment failures after six months was very similar to that mentioned by Col. Marshall. In 105 cases there were 15% of failures, of which 13% were clinical relapses. So far as the evidence went—and it did not go very far as yet—it appeared that the anticipated results from penicillin therapy were not far short of those obtained with the standard method. Clearly, however, the comparison was speculative and scarcely to be justified by the present state of knowledge. A vast amount of information must now be available in the War Office, and it was disappointing that the cases cited amounted to no more than 270. It seemed to him that there was a good case for setting up an organization which would follow these men into civil life and do everything possible by co-operation with the public clinics to obtain information as to their clinical conditions during the next three years. Col. Marshall, who had done well to initiate experiments which would help to lower the incidence of relapsing infection, had no deaths in the 360 cases he had treated, and from this experience there were certain aspects of the value of penicillin which it was legitimate to stress even at this stage. One of these was the importance of such a therapeutic measure for uncooperative patients in civil life. The view had been expressed that the majority of early syphilitics would get well with a treatment generally regarded as inadequate, but there would be a proportion whom it would be difficult to get well even with a full and adequate treatment. It might be that when the optimum dosage of penicillin was known this problem would solve itself. The antisprirochaetal effect of penicillin was not in doubt, but its ultimate value in the treatment of syphilis was very far from having been assessed. Such an assessment was dependent on lapse of time and procedure of investigation. The urgent need was to assess by means of a follow-up the large number of cases which had been treated during the last eighteen months.

Controlled Investigations Needed

Brig. T. E. OSMOND said that he remembered well the enthusiasm with which "606" was hailed when it came in, but, after the apparent cures, relapses began to occur. It seemed to him that penicillin was in many ways comparable with arsenic. Inadequate treatment was liable to be followed by relapses. The tendency had been to increase the amounts of penicillin, and he believed this would and should continue. It might be that they ought to use ten times as much as they had been doing. He attended an Anglo-American conference in Paris last year, at which the results reported from the British Army were not nearly as good as those from the American; there was no explanation why this should be so. Penicillin should be supplemented by both bismuth and arsenic, and increasing amounts of all three drugs were required as the age of infection increased. It had always been difficult to distinguish between relapse and reinfection, and he had been very sceptical of the latter. He thought that all cases should be labelled relapses, otherwise there was danger of overestimating the effectiveness of the treatment. He pleaded for the setting up of a central institute to guide and overlook all tests, especially tests in public laboratories. Penicillin in any reasonable dosage would kill off 99% of the spirochaetes, but something was needed to deal with the other 1%. No doubt penicillin was a more effective remedy than any of the arsenicals, but it would be many years before it was known how effective it was, and whether its use was likely to be followed by later manifestations, cardiovascular or neurological. They had a wonderful remedy in their hands, but they needed a series of controlled investigations.

Surg. Capt. LLOYD-JONES described the follow-up of an investigation concerning 223 cases of primary and 72 of secondary syphilis, all of them diagnosed by the finding of the spirochaete, and treated with penicillin. There had apparently been 18 relapses over a varying number of months. With the dose now considered minimum—namely, in primary cases 13 daily injections of 300,000 units or 8 of 500,000 units, and in secondary cases 16 daily injections of 300,000 units or 10 of 500,000—there had been no relapse to date.

Congenital Syphilis

Dr. GLADYS SANDES spoke of the treatment of congenital syphilitic children with penicillin. In the florid type of infection,

in which there was a high mortality, there had undoubtedly been an improvement since penicillin was introduced. It had been found better, however, to give some arsenic preparation first, and then after a fortnight to go on with penicillin, the reason being that when penicillin was first given the children tended to get a severe catarrhal reaction, almost suffocating in their own secretions. The dosage had never been less than 20 000 units three hourly, leaving out one administration at night, and this was carried on for five days, a few had been treated with 40 000 units and the result had been apparently just the same. None of the children were over 5 years of age. The results of treatment in cases with bone disease had also been impressive. They responded extremely well and cleared up more efficiently than under almost any other treatment.

Col L. W. HARRISON described an investigation concerning the effect of suspensions of penicillin in oil and beeswax. What he had to say was rather tentative and indeed in the nature of a progress report. Beeswax had been tried in various proportions, but he had come to the conclusion that 3.5% was the best. The concentration of penicillin in the blood serum and in the urine was measured after a certain number of hours. He added that he hoped soon to have at his disposal a supply of penicillin purer than any previously obtainable and that such purer supplies would be generally available.

CLINICAL PATHOLOGY

The annual general meeting of the European Association of Clinical Pathologists was held on Jan 12 at the Glaxo Laboratories, Greenford, Middlesex. Three contributions sent by Dr F. RAPPAPORT from Tel Aviv were read by Prof F. Silberstein.

The first, on improvements of the technique of blood cultures, advised the use of a culture medium consisting of 90% fresh water fish infusion and 10% digest broth, the addition of small amounts of beef-liver, beef brain, egg yolk, starch, glucose, liquid, and *p*-aminobenzoic acid made the medium suitable even for the most exacting bacteria. The medium was kept under partial vacuum in an atmosphere of air containing 10% CO₂. The fresh water fish medium contained proteins not susceptible of coagulation by heat. A new method of skin disinfection and the use of a selective medium prepared by adding small amounts of gentian violet (between 10⁻⁵ and 10⁻⁴) to the basic medium described above enabled Rappaport to use capillary blood for culture.

In the second contribution, on collection of blood for examination of organisms of the enteric group, Rappaport recommended that blood should be taken into sterile throat swab tubes so that the clot formed and retracted around the swab, the clot could then be transferred with the minimum of interference into a tube of the same size containing a 3% glucose-bile culture medium. In the presence of glucose ferment a coarse precipitate was formed, absence of such a precipitate after 24 hours' incubation excluded the presence of organisms of the enteric group. The serum remaining in the original tube was used for routine agglutination.

The third contribution suggested technical improvements on the concentration and culture of tubercle bacilli, it advocated the use of both acid and alkaline digesting solutions and neutralization with the appropriate respective solution in the presence of methyl red and thymol blue as indicators. The acid solution consisted of equal amounts of concentrated sulphuric and phosphoric acid, the presence of the latter had a buffer effect in the process of neutralization.

Mr W. B. EMERY spoke of the preparation and purification of liver extracts, showing the satisfactory results obtained in initial treatment of cases of pernicious anaemia by the injection of highly purified extracts containing in some instances as little as 1 to 3 mg. of solids. He recommended that a standard unitage be introduced in this country similar to that used in Canada and the U.S.A. Mr J. T. MARSH showed various penicillin preparations and appliances developed in the last months. Prof S. JELLINEK showed photographs and drawings from specimens of lesions produced by electricity.

Dr G. UNGAR summarized the results of his experiments on the significance of bleeding time, and reported the isolation from the spleen of a substance which greatly reduces the bleeding time and is liberated after injury into the blood stream by means of hormonal influences.

Dr H. S. BAAR (in collaboration with Prof L. G. Parsons) presented clinical and pathological details of four cases of infantile encephalitis, from each of these a virus was isolated which when transmitted to laboratory animals produced an infection closely resembling toxoplasmosis both macroscopically

and serologically. Extensive search of the infective material, body fluids and pathological specimens had failed, however, to demonstrate typical toxoplasma organisms. He also showed three cases of pituitary cachexia in childhood, two of these were due to large colloid cysts.

Dr G. E. WACHTEL produced evidence that the intravenous injection of homologous and heterologous seminal fluid induces hypertrophy of the uterus in spayed and half-spayed immature female rabbits. A gonadotrophic effect on the ovaries had also been noticed; it remains to be shown whether this is a direct effect on the ovary or is brought about via the hypophysis.

Dr S. SEVITT showed an improved instrument for liver biopsy with which suction through a syringe can be applied concurrently with the introduction of the needle into the liver.

GAS-AND-AIR ANALGESIA BY MIDWIVES

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on Jan 25 Dr NINIAN FALKNER (chairman, Central Midwives Board, Eire) opened a discussion on "Proposed Compulsory Training of Midwives in the Administration of Nitrous-oxide-and-air-Analgesia."

Dr Falkner said that the Central Midwives Board in Ireland had recommended that new rules should be adopted making it compulsory for student midwives to receive training in the administration of nitrous oxide and air analgesia. The Central Midwives Board in England had already approved these rules. Any midwife qualifying in England after July 1 this year would come under the amendment of Rule 42. As reciprocal agreements existed between the Central Midwives Boards, it was usual for the rules and training in Eire to keep in line with the rules and training of the English Board.

Dr E. A. KEELAN (the president) considered that if the gas-air machines were used casually they would not always be successful. He recommended that nurses and midwives should receive special training in their use, this could be done in a series of lectures given by anaesthetists.

Prof O. DONEL BROWNE said he was altogether in favour of the proposal. The training should be given by anaesthetists attached to hospitals and not by other midwives or doctors. He had used the gas-air apparatus himself when it was first introduced and he stressed the importance of giving it in time to the patient. He doubted if the percentage of gas and air (45%) given by this machine provided enough analgesia, and asked if there could not be a machine which would give greater relief from pain. Finally he pointed out that, as nurses were good at giving chloroform, he did not see why they could not be just as efficient in the administration of gas-air analgesia.

Dr BETHEL SOLOMONS was all in favour of midwives being allowed to give analgesia if it could be done without danger to the patient. If there was any danger at all, the law would have to be changed so that midwives could issue death certificates. In the Dublin Maternity Hospitals it would be necessary to appoint a full time anaesthetist.

Dr R. W. SHAW agreed with Prof O. Donel Browne that the presence of an anaesthetist in any obstetrical operation was a necessity but he thought it would be difficult to obtain the services of an anaesthetist throughout all the stages of labour especially in a primipara. There were objections to chloroform being given by nurses, would gas-air be any safer or more efficient, and would the nurses and midwives be able to use it proficiently?

Costs and Quantities

Dr ALEX SPAIN said that they used gas-air analgesia very extensively in the National Maternity Hospital. The cost was considerable, in one year they had paid £625 for gas alone for the labour ward, and a trained anaesthetist would be an additional expense. In 1942 they used 22,600 gallons of nitrous oxide, and this figure rose to 188,400 gallons in 1945. He pointed out that the training was not difficult and there was no danger. Over a period of three years in the National Maternity Hospital gas-air analgesia had never caused them a moment's anxiety. The machine needed very little supervision and the patient could easily learn to use it. He agreed that 45% nitrous oxide was not sufficient to relieve pain, they used machines which gave a little over 60% and they were very satisfactory. He recommended the use of chloral hydrate and bromide during early labour, and thought that midwives were entitled to use it.

Prof. J. F. CUNNINGHAM said that it would be ideal always to employ an anaesthetist to give gas and oxygen, but expense and the time factor had to be considered. Chloroform still held its place and would continue to do so, especially in domiciliary and country practice, until something safer was found to replace it. He did not think that it was safe for nurses to use it without a doctor being present, and if they were going to be trained how to use the gas-air machine they should also be trained how to administer chloroform.

Dr. ALAN THOMPSON said that the gas-air machine might be awkward and had many drawbacks, but one advantage was that it could be used intermittently over a period of several hours. This could not be done with chloroform or the barbiturates.

Dr. J. A. D. DEENY (Chief Medical Adviser to the Department of Local Government and Public Health) told the Section that Dr. Ward (Parliamentary Secretary to the Minister for Local Government and Public Health) was prepared to approve of compulsory training of midwives in gas-air analgesia, but that he was inclined to proceed cautiously in the use of this apparatus as he did not think the average midwife in Eire would be very efficient in its use. Newly qualified midwives could be trained to use gas and air, but it would not be easy to train the older midwives.

Dr. FLORENCE MCCLELLAND said she had received the early part of her training with Dr. Minnitt, who invented the machine for gas-air administration. She was disappointed with the machine on the whole, but thought it might be helpful in isolated cases, such as primigravidae with a long first stage of labour. The patient should be trained to use it during her antenatal period; only the patients trained in its use got benefit from it. The 45% mixture was much too weak to relieve severe pain. She did not recommend giving 60% over a prolonged period, as in a trial of labour or where there was any difficulty. This apparatus was not the real answer for universal relief of pain, although it was very useful. In her practice she used cyclopropane almost invariably for normal or forceps delivery. She condemned the use of chloroform, either intermittently or even for a short anaesthesia for delivery, as she had seen acute atrophy following chloroform administration. It might be safe in 99% of cases, but one did come across a patient quite intolerant to the drug. There was no means of knowing what the state of a patient's liver was, and one was not justified in using such a toxic drug. She recommended the use of ether when nothing else was available.

Dr. T. J. GILMARTIN quoted Guedel, who introduced nitrous oxide analgesia in America in 1911, as saying: "There is no more dangerous application of nitrous oxide than its use in obstetrics by the inexperienced. . . ." Claims for success with this technique varied, and he was not satisfied from his own experience that it afforded complete analgesia. It was, however, a step in the right direction towards analgesia and away from amnesics like nembutal. He concluded the discussion by saying that everybody agreed that the Central Midwives Board was justified in bringing this proposal into operation, and that the training schools had adequate provision for dealing with the matter. The necessary apparatus should be obtained, and salaries should be found for those skilled people who would have the responsibility of training the midwives and nurses in the administration of gas-air analgesia.

STATISTICAL STUDY OF INFECTIOUS DISEASES

In a paper read before the Royal Statistical Society on Feb. 27 Prof. MAJOR GREENWOOD pointed out that, although all civilized persons now recognize that infection is a biological process, even as recently as a century ago very intelligent observers thought that epidemics might be due to "atmospherics" or miasmatic factors and that influenza was not an infectious disease at all.

Judgment whether a disease were or were not infectious or contagious was based upon statistical reasoning. Even now statistical arguments were of great importance because there might be difference of opinion as to the vehicles of infection—for instance, whether droplet infection or contamination of water or food or conveyance by biting insects played the principal part. Epidemic poliomyelitis was a case in point. Prof. Greenwood described various statistical methods in use, in particular the study of the time interval between successive cases

in families, and suggested that more work should be done on sets of cases. He then turned to the quest for a "law" of epidemics. The continued existence of mankind proved that epidemics did come to an end, and various medical statisticians had attempted to discover why. One of the first was William Farr, who suggested as a possible "law" the so-called normal curve, but subsequently proposed a rather more complex form by the use of which he predicted—with fair success—the way in which a terrible outbreak of cattle plague would decline several weeks before it did decline.

In more recent times Ronald Ross and John Brownlee devoted much mathematical ingenuity to the elucidation of epidemic forms, while the late Prof. W. W. C. Topley, in collaboration with Prof. Greenwood and others, spent many years on the study of epidemics artificially provoked in herds of mice. Brownlee was of the opinion that epidemics did not usually come to an end because all those exposed to risk and capable of being infected had been infected, but because from the very beginning of the epidemic the infective power of the organism waned. Prof. Greenwood pointed out that there was experimental evidence that this apparently paradoxical hypothesis might be true, but not enough to permit one to regard it as a general explanation. He suggested that the whole subject needed the attention of young mathematical statisticians, because the analytical difficulties of the problem were great.

RADIOLOGY OF THE CHEST

At a meeting of the Manchester Medical Society on Feb. 6 Dr. E. D. GRAY read a paper on "The Present Position of Radiology of the Chest."

He reviewed the various methods used in x-ray examination of the chest, and emphasized the importance of preliminary screen examination; there was a tendency nowadays to rely exclusively on films. Apart from the additional information obtained by fluoroscopy, it was possible during this examination to plan the subsequent radiographic procedures to the best advantage—a method of much more value than the routine exposure of multiple films without previous investigation under the fluorescent screen.

The importance of the antero-posterior chest radiograph as an adjunct to the standard postero-anterior was stressed, especially in the demonstration of small, posteriorly situated lesions, which in the one view might be obscured by superimposed shadows of the bony thorax. The principles underlying the use of tomography, bronchography, and screen photography were briefly described. Illustrations were given of a number of pitfalls, most of which could readily be avoided if the observer were familiar with the technical and physical principles of chest radiology. Mention was made of the help afforded by radiology in the study of the anatomy of the lungs, notably of the bronchial tree, the interlobar fissures, and, more recently, the pulmonary vascular supply.

If an experienced observer could say in any particular case that no abnormality had been detected, this negative finding could generally be relied on in the exclusion of many of the important intrathoracic lesions. If clinical suspicion continued, however, there should be no hesitation in repeating the x-ray examination after an interval; in some conditions there was a latent period before the radiological signs became evident. The interpretation of positive radiological findings was not so simple. Occasionally the x-ray appearances were characteristic enough to lead directly to the diagnosis; more often they had to be correlated with the clinical findings. Some cases were so obscure, both clinically and radiologically, that it might be impossible to arrive at a diagnosis from a single examination, and help must be sought from serial radiographs taken at suitable intervals.

In the subsequent discussion Dr. R. ELLIS referred to the work of previous Manchester radiologists, such as Barclay, Paterson and Twining, and to the great value of good co-operation between physician and radiologist. Dr. JESSEL pleaded for a more careful clinical examination and history-taking in cases of early phthisis. In answer to a question by Dr. LUXTON about iodized oil, Dr. Gray said that it should be avoided if at all possible until all other methods of examination, including bronchoscopy, had been tried.

Correspondence

National Research in Tuberculosis

SIR.—The letter of Dr George Luntz (Dec 1, 1945, p 781) raises a matter of national importance. Tuberculosis costs the country many millions of pounds every year and destroys or cripples thousands of persons in the prime of life, and yet our efforts to combat the ravages of this scourge are still spasmodic and half-hearted. This is not due to any lack of enthusiasm on the part of those who devote their whole lives to the prevention and treatment of the disease. One has only to attend a few meetings of the Tuberculosis Association to realize the keenness of its members, the interest which they take in new methods of treatment, and their readiness to assist sufferers from this disability in every possible way. But progress in the past has been very largely due to individual effort struggling against the complacency and ignorance of both patients and the general public. The Joint Tuberculosis Council is a body composed of some of the leading authorities on tuberculosis in the country, but it lacks the necessary financial backing to provide its efforts with the success they deserve, and its excellent reports and memoranda waste 'their sweetness on the desert air'. The National Association for the Prevention of Tuberculosis has made heroic efforts for the last forty five years to rouse the nation to realize its responsibilities with regard to the prevention of this disease. Yet, in spite of all this good work, which is almost entirely voluntary, we are still unable to prevent persons becoming tuberculous or to offer them a cure, and the infection continues to take its toll of children and young adults as it passes through the population practically unchecked.

Our knowledge of the pathogenesis of the disease is very incomplete and any attempts at prognosis are always uncertain and often fallacious. This unsatisfactory position is mainly due to lack of organized research, as regards both prevention and treatment, and the time is ripe for money and labour to be devoted to this purpose so that a concerted effort may be made to reduce this national liability. The experience and advice of the three bodies I have mentioned could be taken to assist an appointed team of experts to devise and put into execution programmes of research in tuberculosis, adequately backed by the necessary financial support from Government funds whereby it should be possible to discover the cure and determine the best methods for the prevention of the spread of the disease.

Those responsible for the treatment of tuberculosis would be only too anxious to adopt new methods which are recommended by a competent research organization. In fact, in many sanatoria under local authorities a considerable amount of research work is already performed, but it is at present individualistic and tends to run along separate channels which flow independent of each other. There is need for collaboration in this work, so that the various efforts may support each other in a united one to discover a cure for the disease.—I am, etc.,

Berkhamsted

FREDERICA HEAF

Tuberculosis in Childhood

SIR.—As a tuberculosis officer I read with interest Dr P W Roe's letter (Feb 16, p 256). I should like, however, to dispute his statement that nobody cares for the children running about the house of a tuberculous adult. It is the duty of the health visitor to warn the parents of the danger to the children, and to require them to bring the children to the dispensary to see the doctor. It is then my practice to do a Mantoux test, to x ray all with a positive reaction and to observe all cases, negative and positive, so long as they are still in contact with the tuberculous case. Sometimes, of course, the parents pay no heed to what the health visitor says, and I am sure I would be very glad if the general practitioner would reinforce her remarks, to see that these children are properly investigated at the dispensary. Though the G.P. may not be able to order an x ray examination he can still send these children to the T.O., who can do so.

Furthermore though I have always been a keen advocate of health centres and a balanced State medical service I do not

think that any useful purpose will be served by equipping health centres with an x ray plant, even with a skilled radiographer. I know very few G.P.s who are able to make an intelligent reading of a chest film to-day, and though they might acquire that skill no doubt, I see no reason why they should trouble when there is already a fully equipped public health service ready and eager to do this work.

I agree, however, that it is almost impossible at the present time to do more than just follow up these cases. Unless there is something definitely pathological we cannot send them to a sanatorium. Contact may be broken by removing the adult to a sanatorium, but the chronic case is often still positive when he returns. We urgently require country "preventoria," to which we might send the child contacts for periodic holidays to stimulate their resistance. These would also be of tremendous help in the family where the mother is the tuberculous patient, as cases arise in which sanatorium treatment has to be refused or drastically curtailed because there is no one to look after the children and nowhere to send them.—I am, etc.,

Bishop Auckland

WILLIAM D GRAY

Lay versus Medical Administration

SIR.—The question put by Sir Frederick Menzies (Feb 16, p 251) on this vital point is both timely and necessary. In the next few months a decision will be made for good or ill which will have profound influence on the future of medicine. Is the chief officer of the administrative unit—regional, divisional, or whatever it may be—to be a layman or a medical man? It is very proper to have a layman as Minister of Health, and it is democratic and wise that under the Minister in the various regions there shall be committees of weighty lay composition, but who is going to direct the very considerable administrative machine which will be necessary both to advise the committee and to carry out its decisions? The personnel will be numerous, there will be many laymen and a few doctors. At the higher levels both professional and non-professional officers will have important functions and a degree of parallel organization may be desirable, but there can be only one head. If this is a layman it is unlikely that he will fully understand and be sympathetic towards the many medical problems that will beset his department. The prominent idea that the layman has some mysterious inherent quality for administration that is withheld from a man who has studied his subject and qualified in it is absurd. It would be equally idle to pretend that every doctor was, *ipso facto*, a capable administrator, but a good medical background is surely not a bad foundation on which to build experience in the administration of a large medical organization.

Some clinicians fondly believe that with medical advisory committees they can do without doctors at head offices. The lay secretary at their hospital has never got in their way. He always does what he is told, and so they think they will similarly "manage" the lay administrators in a new health service. What a cardinal error! Let there be no mistake about this. Advisory committees cannot be given executive functions. Organization there must be and chief officers with considerable powers. We should do everything possible to see that such officers have the necessary medical background and combine the scientific outlook with a practical experience of administration.—I am, etc.,

London N.W. 11

F J BENTLEY

SIR.—Sir Frederick Menzies expresses the hope that the Minister of Health will appoint medical men as the chief administrative officers of regional organizations in the new health services. He might have gone further and insisted that medical men selected for such positions should be chosen only from among those who have had wide and successful experience of the administration of medical services. A medical qualification alone is no guarantee of ability to perform administrative functions. The medical administrator is just as much a specialist in his own line as are those who identify themselves with various types of clinical work. Sir Frederick Menzies, I am sure could suggest where such men are to be found, and so could I, Mr Editor, but after reading your unpleasant attack (with its sneering headline) upon the county medical officer for Essex (Feb 16, p 241), I feel that you would not approve my suggestion.—I am, etc.,

Nottingham.

CYRIL BAYNS

Physical Therapy in Mental Disorder

SIR,—Those who have been practising psychiatry during the past twenty years cannot help having noticed one significant fact with regard to nearly each one of the newly introduced physical treatments of mental disorder. At first it is tried in the most hopeless varieties of mental illness—e.g., chronic schizophrenia. The results prove disappointing. It is then tried in schizophrenia of recent duration; the results continue to be disappointing. The treatment is then transferred to the less malignant forms of mental illness—e.g., the manic-depressive group, or at least schizophrenia with a cyclothymic colouring; a psychotic episode is thus made to clear up more rapidly, but recurrence is not prevented. Finally the neuroses—the milder worries and depressions of life—are attacked, and good recoveries are frequently obtained. A wag has remarked that E.C.T. produces the best results in schizophrenia when the illness is at such an early stage that a diagnosis cannot be made.

The sequence of events noted above has happened with cardiazol, E.C.T., and insulin, and is now happening with leucotomy. Among the ultra-enthusiasts are those who consider that leucotomy should be performed in the earliest stages of mental illness, even where no other forms of treatment have been attempted. Dr. G. W. T. H. Fleming complacently envisages an era when one will hurry to leucotomize a patient aged 60 who has developed a sudden depression with suicidal behaviour (*J. ment. Sci.*, April, 1942, p. 282). One can guarantee that under such circumstances there will be a favourable "recovery" rate, for does not every medical officer of a mental hospital well know that at least 80% of his recoveries (in the major psychoses) occur within the first year of admission anyway, leucotomy or not? But this operation destroys all the finer feelings and emotions, eradicates all the original and creative faculties. Many psychiatrists, like myself, believe that it is worth while to suffer a depression a little longer and obtain a real cure, a restitution to normality, rather than rapidly attain a facile, emotional dementia.

Permit me, Sir, to observe that the greatest advance in the last fifty years in relieving the sufferings of mentally sick people has been the practical application of the researches of Pavlov, Freud, Jung, Adler, and Stekel. Why then is there such a concentration on the physical modes of treatment, with the inevitable neglect of psychotherapy, for there are nowhere near enough psychiatrists available for the pressing needs of the population? One answer lies in the more dramatic and shop-window aspects of the former, especially so far as laymen are concerned. The ordinary public (I have read newspaper reports by journalists who have been invited to watch the fun) can readily appreciate the hum of an electric machine with all its dials and gadgets, or the splendid view of a large, well-fitted operating theatre, complete with shining surgical instruments; but what can the psychotherapist exhibit except an armchair, a couch, and perhaps a syringe filled with evipan or pentothal? here is just no comparison from the advertisement point of view.

And there is another reason why pushing a button is more popular than intense psychotherapy. Anyone can quickly learn the technique of E.C.T., but efficient psychotherapy requires many years of experience, and we are short of well-trained personnel. Very few of us get anywhere near Prof. Jung's ideal—a doctor of wide culture, who has travelled far and experienced much himself in suffering and happiness, who is well read in all the leading schools of psychology, philosophy, and religion, who possesses natural sympathy, patience, and kindness, and who has a keen desire to understand the sufferings of others. Those of us who are enthusiastic earnestly try to live up to such an ideal, but it is very time-consuming, and the work is exhausting. Yes, I must admit, pressing a button is much easier, and a more readily available capacity.

One argument given for intense physical treatment is that in the more malignant psychoses "we must do something." But there is no virtue in furious activity unless this is impelled in a scientific manner. Why must such an attitude be adopted in psychiatry, when the same policy is not followed in other branches of medicine? General physicians cannot "cure" rheumatic valvular disease or hypertension, neurologists cannot cure disseminated sclerosis or the muscular dystrophies, but they do not rush indiscriminately to shock treatments; they seem to be

content to admit honestly that in the present state of knowledge only palliative treatment is available, and that we must hopefully await the results of research. And this impels me to draw attention to a great failing in the organization of psychiatry in this country. The Mental Treatment Act of 1930 (Section 6) gave every local authority the power to expend money on research. How many local authorities have taken advantage of this, and to what extent? But without organized research psychiatry will not progress with any great rapidity. To convulse or to leucotomize hundreds of patients on a conveyor-belt principle in order to be able to boast of astronomical figures to some lay committee is not scientific research.

Finally, I wish to make it clear that, unlike Dr. D. W. Winnicott, I am not opposed to experimental procedures on physical lines in any of the more malignant psychoses, but I strongly object to E.C.T. and leucotomy being used in a non-scientific and indiscriminately wholesale manner.—I am, etc.,

Park Prewett Hospital, Basingstoke.

I. ATKIN.

SIR,—Dr. Winnicott informs me privately that I am mistaken in suggesting that he does not approve of other than psychotherapy in mental illnesses. I am sorry if I have done him an injustice. It seems that our points of view are not so separate as at first appeared. He disapproves of electric convulsive therapy and leucotomy in any case; I feel that they should be used only in selected cases and deprecate their abuse.

It seems a great pity that no indications, no definite canons regarding the application of these treatments have been formulated. It might be suggested that something like the following would be of use in indicating when these therapies were to be employed. Although they appear self-evident such criteria are frequently neglected and no harm can be caused by stating them. (1) Because they are drastic treatments with occasional serious consequences (fractured vertebrae in convulsions, death in insulin coma) convulsive and insulin therapy should be used only after a careful and complete physical and psychological examination has been performed, and after every effort, such as the correction of environmental stress, psychotherapy, and so on, has been made. (2) Because a certain percentage of schizophrenics recover spontaneously, and this usually occurs within two years of the onset of the disease; moreover, because leucotomy is a mutilating treatment, it is absolutely contra-indicated before this period. It is indicated afterwards only when everything else has been tried and failed. In the case of obsessionals a period of five years should be substituted because this illness has less severe social consequences and the patient is more likely to recover spontaneously or with lesser forms of treatment.

In my opinion anyone who rushes in to apply mutilating operations such as leucotomy without using criteria such as those suggested above should lay himself open to an action for maiming, and sooner or later I am sure that this will happen with serious consequences to the operator and his advisers.—I am, etc.,

London, W.1.

CLIFFORD ALLEN.

SIR,—In the debate on this subject there is evidence of some confused thinking. That treatment is at times given unnecessarily, unskillfully, or even with a lack of humanity, may be a criticism of the exponents but not of the methods themselves. It is, however, to be deplored when argument is perverted into personal attack. The reflections on the character of Dr. Jan Frank, made by one of your correspondents in the issue of Feb. 16, are as unjust as they are irrelevant. We had the chance of working with him at Graylingwell Hospital. Because he is a trained psycho-analyst who uses physical treatment to help those beyond other means of relief, we learned much from him of the way humanity and individual insight should guide the doctor in his approach to the patient.—We are, etc.,

ELIOT SLATER.
WILLIAM SARGANT.

Maudsley Hospital, S.E.5.

SIR,—Medical officers who, strange to relate, do for the most part know what they are about will have attended with interest to the counsel of the few that have written with knowledge and authority; they will have been wearied by the quite remarkable fatuity of those who have gone to such trouble and length to

display neither. Without demur—at least, without much—we have seen ourselves described as dishonest, brutal, and feeble-minded. But against the rank bad taste of Dr. C. G. Learoyd (who, for some reason, thinks it necessary to emphasize that he is not a psychiatrist) and his contemptible innuendoes associating the views of Dr. Jan Frank with the methods of "Hitlerite Germany," I know that I am not alone in wishing to protest. I am only surprised that you, Sir, have thought fit to print them.—I am, etc.,

Exeter.

JOHN A. AINSIE.

Stethoscope versus X Rays

SIR,—It has been stated that the discussion at the Royal Society of Medicine under this heading "showed a remarkable unanimity between physicians and radiologists" (*Lancet*, 1945, 2, 784). The correspondence in your columns, I am pleased to note, can hardly be said to have done the same.

As a radiologist who has been dubbed (*Post-grad. med. J.*, 1944, 20, 135) to have "an unhappy aversion to mass radiography" and one who clings "to the traditional gibe of the old school of wooden stethoscopes" and "whose experience apparently differs from the rest of the civilized world," I regret to note, with your correspondent David W. Tough (*Feb. 16*, p. 254), that there are so many so-called chest specialists who can find unanimity or satisfaction in deriding the value of one sense in favour of another. He and your correspondents R. C. Hutchinson (*Jan. 5*, p. 31) and E. Weatherhead (*Jan. 19*, p. 103) have rightly stressed the fact that we have five senses and that the use of every one is essential in diagnosis, for any one may give a clue when all the others fail. The radiograph, good though it may be, is merely one of the aids to vision; and though to the novice and the careless clinician or radiologist its spectacular appearances are overwhelming, this is merely because they have neglected to study the limitations and the best uses of radiology and to cultivate the other senses. They have failed to appreciate what I have described (*Proc. roy. Soc. Med.*, 1945, 38, 555) as "the latent negative radiographic period" and "the positive radiographic symptomless period."

The adoption of radiology as the sole essential for the diagnosis of disease on the plea that progressive tuberculosis and other conditions are symptomless is leading to the serious neglect of the clinical history and other clinical methods. Diagnosis and treatment are being carried out without proper examination or attention to the patient. Consultations are held and decisions made between physician and surgeon, not on the patient but on the radiographs. True, the neglected symbol of clinical methods, the stethoscope, is prominently worn to denote the specialty. If there is any comment which ought to have been made under the heading "Stethoscope versus X Rays," it is that the stethoscope necessitates contact of the physician with the patient but x rays do not. The essential clinical evidence is either not sought or neglected because of the concern over the radiographic appearances; and, still more strange, while all this deference is paid to the radiography, the radiologist's opinion, the person who ought to be in the best position to co-operate and advise on radiographic appearances, is neglected and often studiously avoided. This neglect is often apparent to the experienced radiologist, for he is frequently able to get from the patient (the clinician's request in hospital does not supply it) evidence which helps him to interpret his radiographs. Surely the duty of the radiologist is to supply the clinician with all the evidence which radiology can offer; he cannot do this to the best interests of the patient unless the clinician has made an adequate examination and indicated his findings.

To-day the abuses of radiology—I have recorded the most prominent (*Brit. J. Radiol.*, 1945, 18, 249)—are rampant, and unless checked will bring it into disrepute. It is this we have reason to fear. There is a growing tendency to read more into the radiograph than is justifiable, for we do not yet appreciate the extent of the variations of the normal. Unusual radiographic appearances in the symptomless patient tempt the inquisitive—the more the less his experience in radiology—to explore, with the production of symptoms to the disadvantage of the patient. Serial radiographic study by experienced observers is more instructive and less harmful if combined with intelligent clinical investigation.—I am, etc.,

Birmingham

JAMES F. BRAILSFORD.

SIR,—In view of the recent correspondence on this subject this case may be worth recording.

An old friend of mine, an auctioneer, consulted his doctor to find out why recently he felt so tired out in the evening. He confessed that he was increasing his allowance of whisky to overcome this feeling. His doctor could find nothing to account for his symptoms, and sent him to Harrogate for rest and change. He was put under the charge of a very competent practitioner in that town, who also could find no definite evidence of disease. He returned to work after six weeks, but at the end of a month he again consulted his doctor complaining of the same feeling of exhaustion after his day's work. His doctor then took him to London, where he was overhauled by two well-known consultant physicians. Again neither could find anything definite to account for his symptoms, but one suspected early malignant disease of the stomach and advised a bariatric meal to be done in London. My friend, however, insisted that I should do this examination in spite of the wish of the consultant.

I could find no x-ray evidence at all of mischief in the intestinal tract, and as I thought my verdict would not be accepted as I was unknown to either consultant, with the consent of his doctor I x-rayed his chest, though none of the four physicians who examined him suspected mischief there. The film revealed extensive tuberculous infiltration in both lungs. In fact there was very little lung tissue not involved. In the left middle zone there was a big cavity draining into a bronchus. His sputum was strongly positive. He lived six weeks only after the diagnosis of his condition was made.—I am, etc.,

Newton Abbot.

W. H. STEEF.

Fractured Patella

SIR,—In an article entitled "Fractured Patella treated by Excision" Mr. R. Brooke (*Feb. 16*, p. 231) advocates this procedure for transverse as well as for comminuted injuries. The evidence in support of this recommendation does not seem to me to be convincing. In 35 cases followed up there were 19 examples of transverse fracture; 7 of these were left with some disability. Of 29 cases which he observed personally, 26 were found to have "no deformity." This is surprising as I do not remember seeing anyone who had lost a patella without observing some flattening of the knee when it was viewed in the semi-flexed position, and also appreciable reduction in the circumference of the thigh on the affected side.

It is common ground that excision of the patella breaks the continuity of the rectus tendon and the patellar ligament. This deficiency is not always made good by suture of the lateral expansions of the quadriceps. I have seen a good number of imperfect results. It may be that a final decision as to the merits of excision in the treatment of these injuries should be withheld till the late results of a comparable series of fractures competently sutured have been recorded. Meanwhile, I think that suture with multiply stainless steel wire is the method of choice.—I am, etc.,

Radcliffe Infirmary, Oxford

MAX PAGE.

Transmesenteric Hernia

SIR,—I was very interested to read Mr. Peter Martin's account (*Feb. 16*, p. 238) of his case of obstructive mesenteric hernia.

On Jan. 22 I operated on a patient who was suffering from strangulated transmesenteric hernia. There was a defect in the mesentery of about 1 foot (30 cm.) from the ileo-caecal junction, and the extraordinary feature was that the loop of bowel was strangulated on both sides of the mesenteric defect. The bowel had apparently passed from right to left, and of this 6 inches (15 cm.) had passed back again. The bowel was non-viable, and resection of the terminal 18 inches (45 cm.) of the ileum was performed and end-to-side anastomosis of the ileum to the caecum was effected. The margins of the opening in the mesentery, which were smooth and rounded, measured approximately 2 inches by 2 inches (5 cm. by 5 cm.).

The patient made an uninterrupted recovery and was discharged from hospital on Feb. 15.—I am, etc.,

Liverpool.

JAMES MORONEY.

Nitrites in Coronary Occlusion

SIR,—Standard textbooks on medicine and cardiology invariably state that nitrites are contraindicated in the treatment of coronary artery thrombosis, as well as in the pain of "cardiac ischaemia" due to infarction of the myocardium.

No further explanation is usually given, and one is left alone to reflect on this somewhat dogmatic statement.

The two relevant factors in this case are that the coronaries fill during diastole and that the coronary flow depends on the mean blood pressure. Now the diastolic pressure is little influenced in coronary thrombosis, but there is a sharp fall in the systolic pressure. Thus, although the mean blood pressure is less, the diastolic should still be adequate to fill the unaffected coronaries.

Nitrites are supposed to work by acting directly on the smooth muscles of the arteries, producing relaxation. One may well ask if they have any effect on arteries which are hardened and thickened by atherosclerosis. Undoubtedly they must have, as the efficacy of nitrites is proved in the relief they afford in the treatment of angina pectoris.

Coronary thrombosis, like occlusion of an artery of a limb, probably also sets up a certain amount of reflex spasm in the affected artery, its branches, and possibly in the rest of the coronaries, thus accounting for the severe degree of shock that accompanies this phenomenon. Sir Thomas Lewis suggested that the pain was not due to vascular spasm or local anoxia, but the muscular activity of the heart which liberates a pain-producing factor if the arterial supply is occluded. In cases in which the arterial supply to a portion of a limb is occluded by an embolus, for instance, papaverine has been successfully employed in improving the collateral circulation and relaxing associated reflex spasm until a better blood supply is established. Why can this principle not also be applied to the heart? If coronary thrombosis does not cause instantaneous death it is attended by all the evils complicating infarction of the myocardium. The present treatment makes no attempt to correct this and save a portion of the heart muscle from being transformed into a useless piece of fibrous tissue; furthermore it only partially treats the shock by the administration of morphine. The latter is probably only given because of its analgesic properties, as no other drug will afford sufficient relief from pain.

What, then, is the contraindication to a careful administration of intravenous saline or plasma as well as the continuous use of small doses of nitrites for 24 to 36 hours, or possibly longer? The objection to the use of intravenous therapy would be that, although beneficial in the treatment of shock, it would throw an extra burden on the already diseased heart, while in most other cases of shock the myocardium is relatively sound. Of the use of nitrites one might say that besides further lowering the blood pressure, in organs in which infarction is said to occur, there is an already poor or non-existing collateral circulation and that dilating the other arteries might only make matters worse by increasing the degree of infarction.

I should be grateful to know if, in the opinion of competent authorities on the matter, the use of nitrites and a drip is justified in attempting to save the myocardium from permanent scarring and improve the prognosis in occlusion of the coronary arteries.—I am, etc.,

Mayday Hospital, Thornton Heath

H. JASLOWITZ.

Ocular Signs in P.O.W.s from the Far East

SIR,—I should like to reply to Dr. H. G. Garland's letter (Jan. 26, p. 143) and his criticisms as they arise, as well as add some further notes.

Major Dansey-Browning and I sent our preliminary report for censorship in September, 1945. Its purpose was to draw attention to an ocular syndrome, apparently previously overlooked, before the clinical material was dispersed, a more detailed and extensive investigation on greater numbers to follow. Publication for a variety of reasons was delayed till January, 1946.

It should be borne in mind that we were dealing only with the ocular signs as we found them and as described in the literature. The essential features for stress were: (1) There was no ocular paresis as described. (2) There was no peripheral field constriction as described. (3) The proportion of cases of bilateral retrobulbar neuritis (the use of this term is more fully discussed below) and having a central scotoma to white targets having a similar shape to the toxic amblyopia was high. (4) While reviewing the relevant literature from the ophthalmic aspect we carefully avoided that "slough of despond," dietetic

deficiency theories, for we felt that by doing so we were concentrating attention on a more important feature—namely, the irreversible optic atrophy and its relation to the toxic amblyopias.

The syndrome as described by Dr. Garland is similar to that described under the rarer manifestation of beriberi and pellagra in Manson's *Tropical Diseases* (11th ed., 1940) and in Stitt's *Tropical Diseases* (6th ed., 1942). But in none of these accounts are the ocular signs and sequelae stressed which Major Dansey-Browning and I feel are so important and so frequently overlooked.

I endorse Dr. Garland's thesis that the syndrome is due to a dietary deficiency, probably in the B group of vitamins, but repudiate the cavalier dismissal of the part vitamin B₁ plays. I think it would be reasonable to add to vitamin B₁ deficiency, nicotinic acid deficiency and probably an unknown fraction of the B complex. But although vitamin B₁ deficiency was expected—for one finds it difficult to reconcile deficiency of a fraction of a complex and have little or no evidence of deficiency of the remainder of that complex—yet nevertheless this has been the case, as some figures given below will demonstrate. Vitamin A deficiency was possibly present, in that difficulty in seeing, particularly in a dim light, was a marked complaint among those showing a scotoma during the onset of their visual disturbance; how much should be ascribed to vitamin A deficiency is debatable.

Dr. Garland's objection to the term "retrobulbar neuritis" is understandable, and there is a growing body of opinion that it should be replaced by "neuropathy," but the term was used intentionally for the following reasons: (1) A term sanctioned by use, conveying a clinical picture which finally resolves itself in either primary or secondary optic atrophy and having as a cardinal sign pain on moving the eyes. (2) It brings it into line with the other toxic amblyopias, particularly tobacco-alcohol amblyopia (*vide* Carrol and others). (3) The pathological description, although demonstrating that the nerve lesion is a degeneration and, in so far as the cranial nerves are concerned, irreversible, the presence of congestion of the meninges and haemorrhages does not exclude an inflammatory factor. (4) In quite a proportion of cases was seen the blurring of the edge of the disk and the "moth-eaten" appearance of the papillo-macular retinal fibres, particularly to red-free light, one associates with a post-neuritic optic atrophy, and so "neuritis" is preferable to the vague term "neuropathy" in this instance.

The collaboration between Major Dansey-Browning and myself was broken in November by my being posted, and so I am unable to refer to much of our preceding work. However, these figures are from work done in this centre by me since that date and are self-explanatory.

Of 87 cases examined 62 patients gave a definite history of beriberi. There were 38 who had some treatment for beriberi; this treatment was restricted by supplies, and varied from small amounts of marmite, rice polishings, yeast, thiamin tablets, and injections (injections only for a short while for moribund cases), nicotinic acid, a "green grassy stuff they made themselves," shark oil (vitamin A), and red palm oil (vitamin A). There was a bilateral central scotoma to 3/1000 mm. white target with enlargement of the blind spot and a typical "tailing" of the scotoma directed towards the blind spot in 16 cases, 11 of whom gave a history of pain on moving the eyes as one of the important factors of visual disturbance noticed, and only 4 of these had had any attempt at treatment, which was given solely because they "were very ill, and then only for a short while because supplies were so limited and others as ill as they were." One of these was given "grass extract," one marmite, one yeast, and the worst of all had a few thiamin injections. Only one of the cases showed nerve deafness and had been referred to an otologist. Of the total number 2 alone showed arboflavinosis, looping of the limbal vessels, and gave a history of photophobia and keratitis.

It should be remembered that they were all Category A men before capture, and therefore 30 myopes among them is a rather high proportion. I am under the impression, although I have no notes to confirm this, that there is an equally high proportion of arcus senilis. It appears, therefore, that malnutrition may have some bearing on the incidence of these two conditions, particularly myopia.

In conclusion may I thank Mr. Fitzgerald Moore for a personal communication which has been most helpful, and express my unbounded admiration for those who, with but the most primitive equipment, managed to make vitamin extracts locally

and dispense accurate spherical corrections, the lenses being made from broken car wind-screens and the frames from such material as was available.—I am, etc.,

Military Hospital, Lincoln

W. M. RICH.
Capt., R.A.M.C., Ophthalmologist

Suprapubic Drainage of the Bladder

SIR,—In the *Surgery of Modern Warfare* (p. 668) and in an article by R. Ogier Ward and E. W. Riches it is recommended that in cases of retention of urine due to spinal injury permanent suprapubic drainage should be established by a catheter introduced suprapubically by a method of blind puncture. The patient is to be put in a partial Trendelenburg position, the highest point of bladder dullness mapped out, and then the puncture introducing the catheter is made at this point, or at the mid-point between the umbilicus and symphysis, whichever is the lower. The puncture is to be made in a backward and downward direction. The bladder is allowed to empty slowly for 48 hours. This initial slow emptying is necessary until the track is sealed off and prevents the complication of a contracted bladder at a later stage.

On June 11, 1945, a man of 75 was admitted to hospital with acute retention due to prostatic obstruction. Before admission attempts had been made, without success, to pass a catheter; further fruitless attempts were made in hospital. A very competent house-surgeon, having got the book referred to above, faithfully followed the, very full and very clear instructions. All appeared to go well, no difficulties were encountered, and the bladder was emptied slowly as directed. A few days later the patient's abdomen began to get distended, and for various reasons I was asked to take over the case. The bladder was draining satisfactorily, and at first I thought the condition was one of mild paralytic ileus. However, it soon became evident that there was a partial obstruction of mechanical nature; this never became complete, though it caused great anxiety. By June 25 he was much better so far as the obstruction went, but he developed pneumonia. This was slow to clear up and his heart gave much anxiety. By Aug. 23 he was well enough for prostatectomy. I began by enlarging the suprapubic opening towards the pubis, and, expecting the bladder to be adherent to the anterior abdominal wall, was horrified to find I had opened small intestine. Further investigation revealed that the peritoneal reflection from the bladder was low, only just above the pubis; the bladder had fallen away from the abdominal wall, and the space between was filled with coils of small intestine firmly matted round the track of the catheter. When these latter coils had been separated as far as seemed wise, the damaged intestine repaired, and the peritoneum closed, the patient's condition being still good enough, the prostatectomy was proceeded with. From this operation the recovery was at first surprisingly uneventful. There was no intestinal trouble, and by the tenth day the suprapubic wound was dry, though not superficially healed, and he was passing urine normally every two hours. On the twelfth day there was haemorrhage into the bladder with clot retention; this was overcome by washing out. On the fourteenth day the heart began to give trouble, but settled down again, and he went home on Sept. 28.

From then he was well until just before Christmas, when acute intestinal obstruction developed and he was readmitted to hospital. At the operation on Christmas Day the cause of the obstruction was found, as expected, to be due to adhesions between loops of small intestine. These were divided and he made an uninterrupted recovery.

It is evident that when the original puncture was made the bladder was, by its distension, pressed firmly against the anterior abdominal wall; that the peritoneum was traversed, and that as the bladder emptied slowly, as directed, it fell away, the catheter bridging the gap; small intestine followed the bladder down, surrounding the catheter, and became adherent round the track. It seems to me that puncture as high as described must usually traverse free peritoneum, and that the adherence of the bladder at the puncture site cannot be safely counted on. It may be argued that the operation of puncturing the bladder as described is not intended for cases when a further operation on the bladder is expected, and that had he been left with the indwelling suprapubic catheter no further trouble would have arisen, but I cannot feel that it is very desirable to have coils of intestine matted round the catheter track.

This unfortunate case confirms my feeling that it is much safer, when performing suprapubic drainage, to expose the bladder, strip up the peritoneum, and introduce the catheter under vision. This small and simple operation can easily, if desirable, be done under local anaesthesia.—I am, etc.,

Guildford.

E. W. SHEAF.

Cardiac Massage

SIR,—I would like to support Prof. John Morley (Feb. 2, p. 177) in his objection to the use of intracardiac—or intravenous—injections of adrenaline in cases of cardiac failure during anaesthesia. In the past I have had clinical proof of the fact, long known to pharmacologists, that adrenaline causes the heart to go into fibrillation. Few experiences in surgery are more dramatic or pleasing than to see a needle, inserted into the heart of an apparently dead patient, begin to swing from side to side, like an inverted pendulum, in time with the returning pulse. I know of no method of stimulating the heart more certain, speedier, or simpler. I find the spinal needles of Pitkin or Howard Jones very suitable for the puncture, as they are long, fine, and usually ready sterilized on the anaesthetist's trolley. The vital importance of speed cannot be over-emphasized, for there is much evidence to show that cardiac cessation for over 1½ minutes results in irreversible cerebral changes, especially in the middle-aged and elderly. I have had two cases, and I know of others, in men of over 65 years of age in whom the heart has not been stopped for more than 1½ to 2 minutes before it was re-started by needling. Both of these men showed mental changes similar to those met with in senile imbecility; these changes persisted for five to seven days, and subsequently the patients showed a complete amnesia for this period.—I am, etc.,

Liverpool, 1

J. B. OLDHAM

SIR,—While supporting Mr. Hamilton Bailey (Jan. 5, p. 29), Prof. John Morley (Feb. 2, p. 177), and Mr. Harold Dodd (Feb. 16, p. 252), I would like to point out that much of the information required by surgeons and anaesthetists on this important matter is contained in an article called "Cardiac Resuscitation" in the *Journal* of Sept. 21, 1935 (p. 540).—I am, etc.,

Glasgow Royal Infirmary

W. B. PRIMROSE

SIR,—Mr. Hamilton Bailey is such an eminent surgeon that it is with diffidence I join issue with him in his statement that adrenaline injection is of little or no use in cardiac failure (Jan. 5, p. 29), or stoppage of the heart in certain conditions. Dr. Carl Bodin, of Budapest, about 23 years ago in an exhaustive letter to the *Lancet* recorded a remarkable case of resuscitation by the injection of 1 ml. of 1 in 1,000 adrenaline chloride into the right ventricle, the patient being dead for three minutes. All signs of life had gone—corneal reflexes, respiration and pulse, and no heart sounds. The patient being very obese, with a 3-in. (7.5-cm.) needle he injected 1 ml. adrenaline chloride into the right ventricle. He advised that the best position for this was to inject into the fourth left intercostal space, keeping close to the sternum to avoid the internal mammary artery. This seems to be the safest area for the right ventricle; it avoids the conus arteriosus and the anterior descending branch of the left coronary artery.

I followed this method many years ago in a patient dying of pneumonia. He was in *extremis* and moribund; he revived remarkably, but unfortunately his family got him out of bed to relieve his bladder in two hours' time, and he collapsed. One should not wait, of course, until all signs of life disappear, but I think the general practitioner should attempt this method in more cases of the dying and possibly some lives might be saved.—I am, etc.,

Southall

JOHN R. O'BRIEN

Anaesthesia

SIR,—Dr. W. A. Bellamy (Feb. 16, p. 252) falls into the common error of assuming that so-called modern anaesthetic methods are more difficult of accomplishment and produce less efficient results than those he describes. I always try to impress on people that the seemingly more elaborate procedures are in reality much easier for the anaesthetist and much more satisfactory for the surgeon and patient than some of the apparently simpler ones. Take for instance a common emergency. A well-built muscular man is admitted with a diagnosis of perforated gastric or duodenal ulcer. The abdomen is as rigid as a board and the patient frequently groaning in agony.

According to Dr. Bellamy anaesthesia is induced either by open ether or by the very simple Boyle's apparatus. Even a skilled anaesthetist often fails to produce anything approaching satisfactory operating conditions using such methods. Relaxation is often incomplete, and the exaggerated diaphragmatic movements so characteristic of deep ether anaesthesia are a source of embarrassment to the surgeon.

The method I prefer, though seemingly more complicated, is in reality much easier to perform and produces infinitely better conditions for the surgeon. The patient is put to sleep with an intravenous barbiturate and a bilateral intercostal nerve block performed. Nobody could describe this as difficult. It produces absolute relaxation of the abdominal wall. Anaesthesia is then maintained with light cyclopropane using to-and-fro absorption, certainly one of the simplest and least toxic general anaesthetics. No endotracheal tube is needed, and frequently a pharyngeal airway can be dispensed with. The operative field is very quiet and recovery is quick and uneventful in contrast to the prolonged period of depression which follows a deep ether narcosis.

One could cite numberless examples showing that the much-maligned modern methods are much simpler and safer than the older ones.—I am, etc.,

Bodelys Park, Surrey.

F. G. ETHERIDGE.

SIR,—I never quite know whether anger or disappointment is the more prevalent when I read letters like that of Dr. Bellamy; I trust, however, that my reply is more in sorrow than in anger.

There must be many hundreds of anaesthetists in the English-speaking countries who are devoted to their specialty and who spend a great deal of thought on how they can make their patients safer for surgery. Many of us even correspond across land and ocean to the same end. A number of us in Britain, banded together under the auspices of the Anaesthetics Section of the R.S.M., attend meetings where we discuss and criticize innovations and exchange views. Were Dr. Bellamy to attend our gatherings I can assure him that he would find no attempt to wrap up our art "in a halo of Heath-Robinson mumbo-jumbo" but, on the contrary, a sincere and honest attempt to probe the many mysteries still hidden from us. We even publish our proceedings. This being so, I feel rather hurt that Dr. Bellamy should have been so unfair.

I agree that all new things are not necessarily good things; but all good things were once new, and had they not been investigated at the time would not have survived to benefit mankind. There is no need to pursue this moral. Dr. Bellamy asks, in effect, why anaesthetists do not stick to the same techniques as were prevalent twenty years ago. I reply: for the same reason that we no longer travel between London and Aylesbury by stage coach; we have discovered better means. Surgeons have greatly increased their surgical repertoire during twenty years, and embark upon heroic procedures many of which are only made possible by modern methods of anaesthesia.

With regard to teaching, Dr. Bellamy may derive some comfort from the fact that at least one hospital is considering a course to teach undergraduates anaesthetics at special operating sessions upon patients selected to withstand the rigours of "simple" anaesthetics, thus ensuring that students may gain experience *sans* "mumbo."

The remarks about deaths during anaesthesia are misleading, and the fallacy involved has only recently been exposed in your correspondence columns. Suffice it to recall that one of the many causes why these fatalities do not decline is the increase in the surgical treatment of conditions once thought inimical to surgery. Another is the ill-advised administration of pentothal either to unsuitable subjects or in unsuitable surroundings with no resuscitative drugs or oxygen at hand in case of difficulties. The administration of both chloroform and pentothal might be summed up in the following slogan: Dead easy—easy dead. A better appreciation of this fact might lead to a marked fall in the number of anaesthetic fatalities.

To show that I really am not entirely consumed with anger may I extend a hearty welcome to Dr. Bellamy to attend the next general meeting of the Anaesthetics Section as my guest in order that he may assure himself that no witchcraft goes on. Time and date: 5.30 p.m., Friday, March 1. Subject: Curare.—I am, etc.,

London, W.1.

A. H. GALLEY.

SIR,—Dr. Bellamy (Feb. 16, p. 252) has cast a rather obvious fly. But in case his devoted head should remain bowed and not notice an important point: the percentage of deaths under anaesthesia, which is not of necessity the same as anaesthetic deaths, may not have decreased in the last fifteen years with the advent of modern methods and apparatus, but the extent and severity of surgical procedures justifiably undertaken to-day on cases that were previously considered unfit surely make amends for the apparent complexity of the apparatus.

There are still indications for the use of open chloroform anaesthesia in surgery and obstetrics, and it can be employed in place of much apparatus which appears complicated to the occasional anaesthetist. The "professional anaesthetist," however, is prepared to use whatever form of anaesthesia is most conducive to the patient's well-being and post-operative comfort and the satisfaction of the surgeon's requirements. I submit that these criteria are more often satisfied to-day than they were fifteen years ago.—I am, etc.,

Cambridge

ANGUS SMITH,
Squad Ldr., R.A.F. Medical Service

Spinal Analgesia in Operative Obstetrics

SIR,—About six weeks ago I made the arduous journey to Croydon in order to watch Mr. Rufus Thomas perform a lower-segment Caesarean section under heavy nupercaine analgesia. At that time I was apparently the first visitor from London to do so, although Mr. Thomas's articles on the subject go back for some years, so I feel that my observations may be of interest. I had expected to see a competent performance, but what I actually saw was something far more than that.

I have witnessed many lower-segment Caesarean sections performed with more or less ease and perfection by many different surgeons, and I have personally performed the operation under most types of anaesthesia with the exception of spinal analgesia. It has always seemed to me that the only real difficulty in the performance of this operation lies in the accessibility or otherwise of that portion of the uterus which forms the operation field. Even the most expert anaesthetists admit that it is not easy with inhalation anaesthesia to maintain an anaesthetic which is both light enough not to injure the baby and at the same time deep enough to give adequate access to the pelvis. From what I saw at Croydon it seems to me that these difficulties are eliminated under heavy nupercaine analgesia.

From start to finish the operation went like clockwork. There was no hurry of any sort, but why should there be as the analgesia lasts for some hours? The abdominal wall was relaxed in a manner which must be the dream of the average surgeon performing the lower-segment operation. Ease of access to the lower segment was maximal, as also was ease of delivery of the head. Bleeding was practically non-existent, and the uterus expelled the placenta spontaneously through the uterine wound without interference. The baby, which weighed over 9½ lb. (4.3 kg.) entered this world in as fit a condition as I have ever seen. Completion of the operation was carried out with a maximum of care and deliberation and a minimum of worry and haste.

So much for the technical details, but what of the patient's reaction? So far as I could see she had practically none. The analgesic was given by the operator himself, and the patient did not apparently know what type of anaesthetic she was due to have beforehand. Before the operation was due to start, the resident anaesthetist was summoned, and throughout the operation he recorded the blood pressure at regular intervals. I understand from Mr. Thomas that should the systolic pressure fall below 100 he gives an injection of methedrine into the uterine wall, but on this occasion it remained at about 130 throughout. After delivery of the baby the patient complained of slight nausea, which was immediately controlled by inhalation of a little oxygen. It has been suggested that Mr. Thomas's results must depend on a well-trained team. It seemed to me that the team consisted largely of the surgeon himself, as the duties of the anaesthetist were merely to record the blood pressure and, if necessary, to administer a little oxygen if the patient complained of nausea. The assistant on this occasion, I may add, was acting for the first time.

It does seem to me that there is no place in medicine for prejudice, yet many surgeons are still objecting to all forms of spinal analgesia for Caesarean section simply because they have been brought up to do so. After all, the two series recorded by Mr. Thomas, and more recently by Dr. Louis Resnick (Nov. 24, 1945, p. 722), total up to over 600 cases without a single fatality. Surely in this instance the old legal maxim of *res ipsa loquitur* applies—the facts speak for themselves.—I am, etc.,

London, W.1.

D. G. WILSON CLYNE.

Morbidity and Spinal Analgesia

SIR.—In following with interest the correspondence on the scope of spinal analgesia in Caesarean section one notices that no reference has been made to morbidity. Complications not leading to death, like invisible exports, do not always figure in the balance sheet. What information have anaesthetists and neurologists on sequelae such as paresis, sphincteric involvement, etc.? Obviously any one operator has probably not enough experience to be able to assess these risks. Are women less prone to these than men? Is the fear of their occurrence justified or mere prejudice?—I am, etc.,

London, W.1

KENNETH BOWES.

Significance of the Erythrocyte Sedimentation Rate

SIR.—May we be permitted to reply to some of the points raised in the correspondence which followed our letter (Oct. 27, 1945, p. 584). Dr. J. W. Shackle (Nov. 24, p. 742) refers to acid-fast bacilli found in gastric juice. In the 7 cases referred to, tuberculosis was produced in guinea-pigs by inoculation of gastric washings. We had read the interesting article to which we think he referred (Yates, Oct. 20, p. 530). Details of the 7 cases we quoted may be of interest. The E.S.R. figures refer to readings obtained in standard Westergren tubes using Heller and Paul 3:2 ammonium and potassium oxalate mixture.

Case No.	Sex	Hb % (Haldane)	E.S.R.			Gastric Lavage (Guinea-pig Inoc.)		Skiagram
			Date	Results		Date	Result	
				1 hr.	2 hr.			
19	M	94	11/2/44	mm. 7	mm. 10	11/2/44	+ve	Assmann focus R. upper zone
21	F	86	28/1/45	7	51	26/1/45	+ve	(?) Primary complex plex L. mid-zone
23	F	94	15/2/45	26	86	23/2/45	+ve	Mottling R. upper zone
26	M	91	11/2/44	12	30	11/2/44	+ve	Bilateral mottling
35	F	94	31/3/45	7	23	31/3/45	+ve	Primary complex R. lower zone
37	F	92	2/4/45	15	44	2/4/45	+ve	Round foci upper zones (R:L)
38	M	104	30/10/44	6	27	30/10/44	+ve	Assmann foci L. apex and infra- clavicular area

We examined fairly recently a woman aged 21 who was a contact of a case of pulmonary tuberculosis. A skiagram taken on May 13, 1944, showed a small Assmann focus in the left infraclavicular zone and slight mottling in the right mid-zone. Sputum (May 12) was positive. The E.S.R. figures (May 20) were as follows:

Heller and Paul Mixture		Westergren		Hb % (Haldane)
1 hr.	2 hr.	1 hr.	2 hr.	
8 mm.	27 mm.	8 mm.	22 mm.	92

The patient died seventeen months later of widespread bilateral phthisis. None of the above E.S.R. figures was corrected for corpuscular volume, but from the haemoglobin percentages it is unlikely that a correction for plethora would have raised the rates appreciably. Further, Wintrobe himself says that methods of correction for the effects of anaemia are crude and artificial.

Dr. K. B. Rogers's letter (Dec. 29, p. 940) contains some statements which call for comment. In the first paragraph, referring to our letter, he says: "They quote experiments performed in Westergren-type tubes, comparing the one-hour reading obtained with the same blood diluted with 1/5 its volume of 3.8% sodium citrate and with Paul and Heller's oxalate mixture."

Reference to our letter will show that we diluted the volume (1.6 ml.) of blood with 0.4 ml. of sodium citrate, which is 1/4 the volume of blood. Presumably Dr. Rogers had in mind the fact that the final blood-citrate mixture will contain one-fifth of its volume of citrate. Dr. Rogers states that we compared the one-hour reading by the two methods and goes on to offer an explanation of our observation that the sedimentation rates of the oxalated samples were not uniformly faster than those of the citrated samples. He says, "The one-hour reading can occur in any part of these curves, thus explaining their variable results." This may be correct, but we compared the two-hour and not, as he quotes, the one-hour reading. The first sentence of the fourth paragraph of his letter conveys the impression that more recent reference to the papers we cited would have elicited information which in fact did not exist in them. "Many of the authors do not give the method they employed in carrying out the E.S.R. . . ." is just a repetition of our statement that "many writers do not state the method they employ." In the fourth paragraph Dr. Rogers says ". . . and unfortunately Dr. Kayne is dead, so I cannot trace the technique he employed." Since our letter does not contain a reference to any personal figures quoted by the late Dr. Kayne for the E.S.R., the effort to trace his technique would have been quite irrelevant to the question under consideration.

Our views on the E.S.R. have been described as "scathing" and "too condemnatory." In our letter we were referring to the variable results which we had personally obtained with two commonly employed methods (the Westergren and the Heller and Paul oxalate methods). We could not, and did not, damn methods of which we had no personal experience. We would repeat that the E.S.R. test as performed and interpreted by many clinicians carries too large an error, particularly in females, to render the results of real value. Certain standards for normality accepted by various authors were given. We have no reason to alter our opinion that if these are accepted many apparently healthy persons will give readings well outside these limits and many cases of active tuberculosis will give readings within these limits. The recent paper by Trenchard (*Lancet*, Dec. 29, 1945, p. 842) supplies ample proof of this latter statement. Except when dealing with such isolated groups as hospital nurses the physician is unlikely to have obtained a "normal" reading for the individual prior to the development of a suspected pathological state. On the other hand, we are in entire agreement with Hilliard that real progress on the lines followed by Whittington and his colleagues is being made. Those who regard the problem of E.S.R. as having been reduced to a consideration of two factors—tissue destruction and corpuscular volume—which can be accurately assessed in a 100-mm. Wintrobe haematocrit-sedimentation tube maintained at 20° C. should peruse Muller's monograph (1943, New York) and papers such as those by Obermer (*Practitioner*, 1943, 151, 43) and Weingarten (*Lancet*, Oct. 27, 1945, p. 526) when they will no longer remain in doubt about the multiplicity and complexity of the factors involved.—We are, etc.,

D. M. KEAY.

D. G. McINTOSH.

Quinine for Induction of Labour

SIR.—Mr. F. Neon Reynolds (Feb. 16, p. 257) states that the use of quinine for the induction of labour is a "thoroughly bad practice which is productive of many stillbirths each year." Would it not have been a good thing if Mr. Reynolds had given actual figures, preferably from his own practice, to justify such an important statement?

I first used quinine for the induction of labour in May, 1931, and have since used it 105 times out of a total of 647 confinements. I have found it a most helpful procedure, and have not had a single stillbirth in all these 105 cases. There is a proper stage in pregnancy when quinine can be used with safety and success. To use it at the wrong time and in the wrong type of case is to court disaster. I am, of course, not an F.R.C.O.G., and not even a D.R.C.O.G., and I have not been within a maternity hospital for 40 years; I am only a rural practitioner with no begowned, bemasked, and begloved assistants to help me; only a district nurse and "an auld wifie to haud a leg." Possibly, had I Mr. Reynolds's qualifications and bevy of assistants I might have his results. However, I

again ask, Upon what facts and figures does he base his statement? and this request includes stage of pregnancy and normality or otherwise of the case. You must know how to carry out a procedure if you are to have success.—I am, etc.,

Tain

E. K. MACKENZIE.

Artificial Pneumothorax Refill

SIR,—Like most of my colleagues who have worked for a few years in sanatoria and chest hospitals, I have given several thousand refills for pneumothorax, and perforated the parietal pleura several hundred times for different reasons. I suppose that it was chiefly luck that kept "pleural shock" away, but I have never seen a case. As to the "humanity and common sense" invoked by Dr. Alastair Allan (Nov. 3, 1945, p. 607) in the cause of local anaesthesia for pneumothorax refills, my memory is most vivid as regards the humane aspect; as soon as I deemed reasonable in view of the clinical and fluoroscopic findings, I abandoned local anaesthesia—after informing the patient that I was about to do so—and plunged my sharp Morland's needle into the previously visualized space. The number of patients who regretted this change was strikingly few; and in fact at one time I deliberately anaesthetized a large number of my "regulars," who usually were given their refill straight, with a view to getting their reactions. They were unanimous to the effect that the straight refill was much to be preferred—time spent was a little shorter, the more nervous of them could "feel" the refill needle in its course through the anaesthetized track, the prick with a sharp Morland's needle thrust through the chest wall swiftly and with a steady hand was certainly no more painful than the insertion of the anaesthetic needle, and finally there was often an aching bruised feeling at the site of injection hours after.

It goes without saying that if there is the slightest doubt as to the clearance of the lung under the proposed site of puncture, the refill needle must by no means be used as a space-seeker. I do believe with Dr. C. F. Hawkins (Nov. 24, p. 742), whose letter I have just read, that pleural shock is no more likely with one sharp needle than with another, though I should be glad to see statistical evidence on the matter.—I am, etc.,

Burgco, Newfoundland.

HORACE D. ROSENBERG.

Homosexuality

SIR,—It was refreshing to see homosexuality ventilated in Mr. Stanley-Jones's letter. Few subjects are so persistently ignored by both doctors and laity. Indeed it might be claimed that one's attitude towards it is a useful index of tolerance, sympathy, and understanding. Even most doctors appear to become "hot and bothered" and full of violent prejudice when it is raised. It is high time that a cooler and more scientific approach were adopted. Our penal laws against it are a disgrace to civilization and a vestige of those abominable days when a man was hanged for stealing a sheep, etc. I would suggest that the air of grand tragedy usually evident on the few occasions when the matter is discussed is out of place. Too much is said about "curing" the condition, and I doubt exceedingly whether it is "now generally conceded that the majority of cases of homosexuality yield to treatment by psychotherapeutic measures." A small draught of Prinzhorn would be salutary to dispel such optimism. The very radical opinions of René Guyon as shown in his *Sex Life and Sex Ethics* are often dismissed as somewhat naive, but are a step in the right direction.

What is wrong with homosexuality? That seems to be the crux of the matter. Can we not say that it is an immature attitude which prevents, except in very rare cases, a completely satisfying love relationship of body, mind, and spirit? In other words a disharmony which allows the part to supersede the whole. Such an immaturity is by no means confined to homosexual relations, but is even more commonly evident in many heterosexual activities. This is admirably brought out by Solov'yev in his famous work *The Meaning of Love*.

It takes all sorts to make a world, and the immature have their parts to play. It is also a commonplace that many great men have shown a more than usual degree of bisexuality. Wagner once exclaimed, "What is art but a way of remembering youth?" So we should not talk too readily of curing homosexuality any more than we talk of curing red hair. Rather it

is our attitude which needs changing. It is true that from the utilitarian point of view homosexuality and many types of heterosexuality cause a diminution of the birth rate. In countries with a more civilized criminal code than ours these are only crimes when they violate the rights of others. Perhaps in another hundred years we shall catch up.—I am, etc.,

G. G. SHERRIFF.

Normal Temperatures

SIR,—The annotation on basal body temperatures and the menstrual cycle (Feb. 9, p. 209) is of great interest. About the year 1900 the "premenstrual wave" of temperature was noticed and discussed by several sanatorium observers. Carefully taken temperatures were for long the best guide we had to the prescription of rest and/or exercise. For instance, *The Open-Air Treatment of Pulmonary Tuberculosis* (F. W. Burton Fanning, 1909) refers to this on page 36. As it was only seen in about half the patients Dr. Burton Fanning thought it was a symptom of tuberculosis. Marcus Paterson regarded it as physiological, and hence his "danger signal," needing bed rest, was 99° F. in man, 99.6° in women (mouth temperatures).

At Ventnor I was satisfied that there was a menstrual cycle. The temperature was taken in the mouth for ten minutes, all necessary precautions being observed. The waking temperatures were 97–97.6° usually, the rise, of a degree or more, showing more clearly than in the daytime, when, of course, the influence of varying activity modified the readings. I missed the "sharp fall," my impression being that the fall was rather gradual, either before or during menstruation. It was more frequently stated and taught that menstruation resulted in a rise of temperature; but this was only associated with considerable pain or malaise among our Ventnor patients.

The use of the clinical thermometer is casual: "a half-minute thermometer; everyone knows that the normal is 98.4" (in centigrade countries it is 37°=98.6°). So far I have rarely met any practitioner who had been taught that a healthy woman might have a normal day mouth temperature of 99.4° at some time in the monthly cycle. Now we have not only confirmation, but explanation; and at last it may be taught to medical students and to nurses in training.—I am, etc.,

Llanishen, Cardiff.

JAMES C. GILCHRIST.

Bornholm Disease

SIR,—The description of Bornholm disease (Feb. 16, p. 242) does not mention what seemed to me its most distinguishing feature in those very few cases I have seen. The combination of an anxious expression, a still abdomen, and an inspiratory check rather than the expiratory grunt of lobar pneumonia seemed to me of considerable importance in establishing the diagnosis on clinical grounds.

The involvement of the neck and shoulder muscles surely suggests referred pain via the phrenic nerve.—I am, etc.,

Richmond, Yorks.

A. F. T. ORD.

The Metric System

SIR,— *Full fathom five (9.5 m.) thy father lies;
Of his bones are coral made.*

While agreeing that the present chaotic system of weights and measures used in medicine should be replaced by the metric system, one may perhaps ask whether the *Journal* is not attempting it in the wrong way. Two most interesting articles that have appeared lately, of a surgeon's experiences in Siam, and another at sea off Deal, have been ruined and made most irritating to read, by such statements as, e.g., "the hut was flooded to a depth of about 2 feet (61 cm.), and the bunks were only 2–3 inches (5–7.5 cm. above the water." Again, that there was "a depth of 5 fathoms (9.5 m.)" and a reference to an "area of 30 sq. miles (50 sq. km.)" and others (I quote from memory) which I am certain their authors never wrote—and in terms in which they never thought. These terms are not used in any medical reference whatever, and the fathom anyway is traditional sea measure that the medical profession has no right or reason (or, I hope, wish) to change. I wonder what would have been the equivalent of a speed in knots?

If we do eventually adopt metric measure, we shall not do so in the way in which the *Journal* is attempting it. In this

week's issue a mixture is given as containing "Pot. brom. gr. x (0.65 g.)" to a dose, and an ointment made up to a balance of 3i (28.4 c.cm.). It is obvious that the dose will become 50, 60, 100 mg., and the volume of ointment 30, 50, 100 c.cm., or similar round figures, avoiding these unnecessary and irritating decimals.

It is useless to try to introduce metric measure by finding exact equivalents to our existing measures; the only way will be to recast the whole system of dose, frequency, etc., at one fell swoop, in a more manageable form, which may attract rather than repel.—I am, etc.,

F. KEITH HAYMAN.

*One important reason for giving the metric equivalent is to help the foreign reader, who will easily translate the exact equivalent into the dosage used in his country.—ED., *BMJ*.

Chartered Society of Physiotherapy

SIR,—I find with surprise that many of my colleagues are unaware of the self-denying ordinance which is incorporated by the Chartered Society of Physiotherapy in their by-laws.

The by-law in question requires them to refuse to treat any patient except under the direction of a registered medical practitioner, and was incorporated in the Royal Charter which was granted to them in 1920. The principle of medical direction had prior to this been completely accepted by members of the Society, since they believed that they would gain much from their association with the medical profession, ensuring as it does continuity of science and practice. It has been said in some quarters that the Society's action in withdrawing recently from the Board of Registration of Medical Auxiliaries was a step towards repudiating this obligation. I am able to state, however, that this suggestion has never been entertained, whilst it is unlikely that the Privy Council would permit such an alteration in the by-laws which would ultimately be to the disadvantage of the patient. Since the members of the Chartered Society have thus largely entrusted their future to the medical profession, it would seem to be just that we should make every effort to co-operate with them in both their private and their public work even more than we have done in the past.—I am, etc.,

London, W.1.

W. S. C. COPEMAN.

Merchant Seamen's Health Ashore

SIR,—As one whose professional activities are solely concerned with the health of the officers and men of the Merchant Navy, I was deeply interested in the article by Mr. James S. Hall (Feb. 16, p. 244). I and other medical officers working in connexion with the Merchant Navy Reserve Pools see the sailor at a somewhat different angle from Mr. Hall. We see him when he is ashore, Mr. Hall when he is afloat; and this may be the explanation of some rather striking differences in the incidence of disease as it affects the Merchant Navy.

Mr. Hall says "pure neurosis was rare." In 5,113 cases of illness or injury causing unfitness for sea-going seen at this Pool between January, 1945, and December, 1945, psychoneurosis accounted for 9% (as against 3% in Mr. Hall's cases). The explanation of this difference probably lies in the fact that group loyalty is strong enough to make a man withhold his symptoms until he gets ashore, when he knows that his unfitness for duty no longer prejudices the safety of his ship or throws extra strain on his shipmates.

Again, Mr. Hall says "venereal disease is high in the scale" (accounting for about 7% of his series). We, on the other hand, find just over half that figure, with syphilis and gonorrhoea about equally balanced. Finally, lest the young ship surgeon, having read Mr. Hall's article, be too prone to dismiss lightly symptoms of peptic ulcer, I would point out that during the same period at this Pool we have had 116 cases of gastric or duodenal ulcer (2%), all confirmed by investigation: hardly "an extremely rare complaint." In short, we find the sailor-man much more neurotic, considerably more dyspeptic, and either less concupiscent or more careful than does Mr. Hall.—I am, etc.,

ALAN WATSON,
Senior Medical Officer,
Merchant Navy Reserve Pool.

London, E.1.

Obituary

W. CAMAC WILKINSON, M.D., F.R.C.P.

Dr. Camac Wilkinson died on Feb. 2 at Virginia Water at the age of 88. For the greater part of his life he devoted himself with unflagging enthusiasm to one cause—the use of tuberculin for the diagnosis and treatment of tuberculosis—and urged its value as a curative agent long after most other physicians had discarded it for that purpose. A disciple of Robert Koch, whom he first met in 1884, and who gave him personal instruction and encouragement in later years, he shared Koch's belief, announced in 1890, that a cure had been found for early cases of phthisis, and from that time onwards Wilkinson advocated tuberculin therapy with polemical pen but dwindling success.

William Camac Wilkinson, a native of Sydney, went to Sydney University as a student of classics and won a scholarship and gold medal on the way to graduating B.A. After gaining further distinction in science at Sydney he came to England to enter University College Hospital, taking the M.B.Lond. in 1882 with first-class honours in medicine and a scholarship and gold medal in forensic medicine. He proceeded M.D. two years later and was elected F.R.C.P. in 1902. At U.C.H. he was awarded the Fellowes gold medal in clinical medicine and other prizes and an exhibition and the Atchison scholarship. Post-graduate study in clinics at Strasbourg and Vienna was the next stage in his career. Returning to New South Wales he became physician to the Royal Prince Alfred Hospital, physician to the ear, nose, and throat department of the Sydney Hospital, and lecturer in medicine and pathology in the university. In 1909 the Royal College of Physicians of London awarded him the Weber-Parkes prize for the best essay on a subject connected with tuberculosis; the title of this essay was "Tuberculin in the Diagnosis and Treatment of Tuberculosis," and a second edition of it appeared in book form in 1912.

In 1910 Camac Wilkinson left Australia to settle in London as a consultant. For many years he acted as honorary director of a tuberculin clinic for ambulant patients in Nottingham Place, W., and gathered around him pupils in the hope of spreading further the doctrine he held. He was also instrumental in founding a dozen other clinics in London and other towns, but they had all disappeared by the end of the war of 1914-18. His publications, apart from many letters and articles in medical journals, included books on *Treatment of Consumption*, which appeared in 1908; *Principles of Immunity in Tuberculosis* (1926); and *Tuberculin: Its Vindication by Technique* (1933), the first part being devoted to tuberculous disease of the eye, and the second to the diagnosis, treatment, and prevention of phthisis. His belief, stated over and over again, was that sanatoria should be reserved strictly for those cases that could not be treated at tuberculin clinics in accordance with his own method. He held that no risk arose from treating open tuberculosis, in ambulant patients, with tuberculin even in large doses, and that it quenched infection at the source. Nothing shook him from this article of faith, or from his conviction that tuberculin had never had a fair trial.

LADY STANTON, M.R.C.P.

Elizabeth O'Flynn, as she was known to her medical friends and colleagues, died on Feb. 1 in the Hospital of St. John and St. Elizabeth from influenza bronchopneumonia. A week before her death, in spite of physical weakness, she was working at the Mothers' Hospital, Clapton, but for years ill-health had made her life a heavy and difficult struggle, calling for courage and constant effort from one with her frail physique.

A correspondent writes:

Those who witnessed her gallant jesting at her own expense when lying ill twenty years ago could not help but pay tribute to that courage which failed neither in the face of severe pain nor in the knowledge that her arm might be amputated in the effort to save her life. Elizabeth O'Flynn studied at the London School of Medicine for Women and in Edinburgh, and when during the war of 1914-18 St. George's opened its doors temporarily to women, she joined that hospital. After qualifying in 1917, she was successively appointed house-surgeon, house-physician, medical registrar, and assistant curator of the museum at St. George's, evidence that her ability was

recognized to be of a high order. By this time her interest in pathology was aroused, and after holding a post in the pathological department at King's College Hospital, she was appointed assistant to Dr. J. G. Greenfield at the National Hospital, Queen Square, and, soon after, pathologist to the Queen's Hospital for Children, a post she held for 25 years until the time of her death; latterly she also undertook the pathological work of the Mothers' Hospital, Clapton. In her younger days Betty O'Flynn could be the life and soul of a party; every year at the time of the Aldershot Tattoo she would join a group of young professional colleagues of both sexes for a picnic outing—occasions which still live vividly in the memory of many of those who shared them with her. With her Irish wit and quickness went a lack of sense of time, and punctuality was never one of her virtues—a fact that involved her in many difficulties. Probably the happiest time of her life was during the short period of her marriage. In 1930 she married Sir Thomas Stanton, K.C.M.G., Chief Medical Adviser to the Secretary of State for the Colonies, and was thus brought in contact with the medical problems of the Colonial Medical Service, as well as with many members of that service. With her husband, too, she enjoyed visits to hospitals on the Continent of Europe and offered hospitality in London to visiting medical men. The death of her husband in 1938 was a shock from which it seemed to her friends that she never recovered.

Elizabeth O'Flynn, before permanent ill-health overtook her, contributed, either alone or jointly, articles on various pathological subjects to the medical journals, including the first description in this country of the changes in the organs in glycogen disease (Bellingham Smith and O'Flynn, 1933).

ERNEST F. NEVE, M.D., F.R.C.S.

The death took place at Srinagar, Kashmir, on Feb. 6 of Ernest Frederick Neve, a "crusader in Kashmir," to apply to himself the title of one of his books. Dr. Neve gave nearly half a century of active service to missionary medicine in northernmost India, and for ten years or more after his retirement he continued to live in the beautiful mountainous country which he had made his home. He was born at Brighton in 1861, educated at the grammar school there, and after spending two years in Germany entered Edinburgh University in 1879 and qualified in medicine in 1882. Quite early in life his eyes were fixed on a missionary career in India, to which an elder brother had already been dedicated, and he spent the next three years in preparation, acting as resident house officer at the Livingstone Memorial Training Institution in Edinburgh. He served also during part of this time as demonstrator in anatomy at the Medical School and senior assistant in the pathological department and senior ophthalmological assistant in the Royal Infirmary.

In 1886, having obtained the M.D., with gold medal, and the F.R.C.S.Ed., he went out to Kashmir, where he was associated with Dr. Arthur Neve at the Church Missionary Society hospital, Srinagar. This institution he continued to serve as honorary surgeon until 1923, and afterwards as consulting surgeon until his death. He was also one of the founders in 1892 of the Kashmir State Leper Hospital, and acted as its honorary superintendent for many years. While immersed in all this work in India he won the Gunning Lister Prize of Edinburgh University in 1889. His early training in ophthalmology proved useful in India, and in 1894 he published in the *Edinburgh Medical Journal* an analysis of 200 cases of cataract extraction. Other contributions to medical literature included accounts of excision in 700 cases of tuberculous glands and of 72 cases of Caesarean section in osteomalacia. His *Crusader in Kashmir*, published in 1928, referred not to himself but to his brother, and gave an account of the medical missionary work of the two of them, its beginnings and later developments in a strongly Mohammedan country.

Ernest Neve was also famous as a mountaineer; he was a foundation member of the Himalayan Club and made the first ascent of Kolahoi and other Kashmir peaks. He revised successive editions of a *Tourist's Guide to Kashmir*, and other works from his pen were *Things seen in Kashmir and Beyond the Pir Panjal*. In the war of 1914–18 he was captain in the Indian Defence Force Medical Corps. In 1918 he received the Kaisar-i-Hind gold medal of the first class for public services in India. He was also made a vice-president of the Church Missionary Society and the Royal College of Surgeons of England elected him to its Fellowship. In 1934 he retired from active medical work. He had been a member of the British Medical Association for fifty years and was a past-president of the Kashmir Medical Association.

Dr. JOSEPH COHEN, of Aldershot, who died on Feb. 4 at the age of 79, qualified as M.R.C.S., L.R.C.P. from the London Hospital in 1896, and held clinical assistantships there before settling in general practice. He had been a member of the B.M.A. for 48 years. A colleague writes: Joseph Cohen, as he would have wished, died in harness. He was engaged in active practice to within three days of his death. He was a general practitioner of the type which has raised our profession to the place which it occupies in the community to-day. His love and respect for his profession made him determined that nothing of himself should be spared in his exercise of it, and he gave himself unsparingly to the service of his patients. The result was that his patients, in return, gave him their deepest trust and affection, knowing that they would never look to him in vain for help, no matter what problem they brought to him. He was "guide, philosopher, and friend" to three generations of many Aldershot families, where the seniors valued his wisdom and the children his kindness and unfailing gentleness. Professionally he never allowed himself to grow rusty, and in later years, when troubled with insomnia, it was always a medical book or the current *Journal* with which he occupied the sleepless hours. Never too old to learn, he was assiduous in picking the brains of his younger colleagues in pursuit of the latest advances in medicine. His standards of professional ethics were unswerving and his conduct towards his colleagues was irreproachable; he demanded as much from them. His knowledge and skill were ever at the disposal of his fellow-practitioners, while his gay cheerfulness was a tonic to patients and colleagues alike. To work with Joseph Cohen was a pleasure and a privilege; the force of his example, both as a physician and as a man, made one better fitted to practise the profession which, in his own small community, he so outstandingly adorned. Another colleague writes: "Old Cohen" was an outstanding example of what is really meant by the phrase "the backbone of the profession." He had practised in Aldershot for longer than anyone could remember; he swore that he had forgotten all his medicine, yet at the age of 79 he was as modern and up to date as his youngest colleagues, and worked as hard as any of them in spite of a cerebral vascular warning 10 years before his death. Cohen showed the courage of a lion when he palpated his own death-warrant. I was asked to see him, and suggested that he should come that very morning, but he declined with thanks, saying that he had far too many visits to do! He was mercifully spared a long illness and died game and cheerful.

Dr. GEORGE CHRISTOPHER ROBINSON, a well-known Knaresborough medical man, died suddenly on Feb. 5 at Holyhead while on his way to Ireland for a holiday. Born in 1878 in County Fermanagh, Northern Ireland, he studied medicine in Dublin and took the L.R.C.P.&S.I. in 1902. Then for 37 years he practised at Knaresborough and held a number of public appointments. He was police surgeon for many years and medical officer to the Harrogate, Knaresborough, and Wetherby Joint Isolation Hospital. He gave up active work in July, 1939, and moved to Harrogate, but later returned to Knaresborough to carry on the practice of his younger son, Dr. Gerald B. Robinson, absent on war service. His elder son is Dr. Terence G. Robinson, medical superintendent of Shields General Hospital. Dr. G. C. Robinson was a prominent Freemason and in his younger days a noted rugby footballer. He joined the B.M.A. in 1923, was elected vice-chairman of the Harrogate Division in 1929 and chairman in 1930.

Dr. GRACE MARGRETE FREDERICKSON DOVER, of the Christian Women's Medical College, Ludhiana, Punjab, died on Feb. 5 at her mother's home at Telscombe Cliffs, Sussex. She was born in India, at Ghoom, in 1898, daughter of the late Rev. John Frederickson. From Queen's Hill School, Darjeeling, she went on to George Watson's College, Edinburgh, and studied medicine at Edinburgh University, graduating M.B., Ch.B. in 1922. She worked for a year in the ear-nose-and-throat department and in the eye department of the Edinburgh Royal Infirmary, and then became senior house-surgeon at the Royal East Sussex Hospital, Hastings. She returned to India to take up the appointment of lecturer on diseases of the ear, nose, and throat at the Ludhiana Women's Medical College and officer in charge of the ear-nose-and-throat department of the Memorial Hospital, Ludhiana. Dr. Dover received a temporary commission as lieutenant in the I.M.S. in June, 1943, and was later promoted captain.

We regret to announce the death on Feb. 13 at Broadway, Worcestershire, of Dr. CHRISTOPHER WILFRED SHARPLEY, who retired to Cutnall Green, near Droitwich, some little time ago after living at Smethwick, Staffs. He joined the B.M.A. in 1905, represented the West Bromwich Division at the Centenary Meeting in London and at Dublin in 1933, and had been chairman of his Division. A student of the Leeds Medical School he qualified M.R.C.S., L.R.C.P. in 1903, and after serving as

house-physician at the General Infirmary at Leeds became casualty house-surgeon at the Hull Royal Infirmary. During the war of 1914-18 he held the temporary rank of captain, R.A.M.C., and acted as radiologist to the 4th Northern General Hospital, Lincoln, and went over-seas to join the 69th General Hospital. After the war he took the Oxford D.P.H. and became M.O.H. and school medical officer for the borough of Oldbury, Worcestershire, and published a series of annual reports on his work.

Dr. ROBERT GEORGE KEVIN, of Belfast, who died on Feb. 16 after an operation for a serious abdominal condition, graduated in medicine in 1908 and took the M.D. of Queen's University, Belfast, and the D.P.H. in 1911. Before settling in practice he had been house-surgeon at the Royal Victoria Hospital and R.M.O. at Purdysburn Fever Hospital. His wide popularity is reflected in the two tributes that follow. W. D. writes: Dr. R. G. Kevin is mourned by a multitude of patients and friends. He was a man of high intelligence, wide knowledge, supreme kindness and skill, unfailing cheerfulness, and tireless energy. His friends could always be sure of obtaining light from him on any medical problem which puzzled them. He was an enthusiastic and skilful fisherman, and his skill with the shotgun was as great as with the fishing rod. The delight of these excursions with him was not only the sport, but his extraordinary knowledge of birds, beasts, and plants, of castle and dolmen which converted the landscape into a fairyland. He knew the serious ordeal that awaited him, but retained his stout-hearted cheerfulness to the last. G. F. C. writes: By the death of George Kevin Belfast has lost one of its outstanding medical practitioners, one who will long be remembered by all who had the privilege of knowing him. A clinician of the highest order, he combined a sound knowledge of the main branches of medicine with a clear and sympathetic understanding of his patient, thereby making his opinion of the highest value. Endowed with a keen zest for life, whatever he did he did with all his might, be it work, for which he had a remarkable capacity, or play, in many branches of which he excelled—he was a good golfer and a keen sportsman: indeed he was never happier than on those days when he could slip away with rod and gun from the din and bustle of the city to the quiet countryside which he loved so much. Gifted with a sense of humour, he had a well-stocked storehouse of anecdotes drawn from the experiences of his daily life. His genial presence and hearty laugh will be greatly missed by all those with whom he worked at the Board for the medical examination of recruits for His Majesty's Forces. He leaves behind him a record of work well done and a heritage of happy memories. To his widow and sisters sincerest sympathy goes out in their irreparable loss.

The Services

Capt. S. Sankaran, I.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Burma.

The following appointments and mentions have been announced in recognition of gallant and distinguished services while prisoners of war:

M.B.E. (Military Division).—Major (Temp.) W. M. MacLeod, and Capt. T. C. N. Gibbons, W. Milburn, A. P. Norman, J. E. Readman, N. S. Seaford, A. F. Stallard, H. T. Tate, and H. W. Wykes, R.A.M.C.

Mentioned in Dispatches.—Lieut.-Col. F. J. O'Meara, Majors W. L. Kinnear, M.B.E., and G. G. E. Smyth, Majors (Temp.) J. M. Fosbrooke and E. Moore, and Capt. J. A. Learner, D. J. MacRae, J. A. S. Mulligan, and T. M. Park, R.A.M.C.

The following appointments, awards, and mentions have been announced in recognition of gallant and distinguished services in the field:

O.B.E. (Military Division).—Lieut.-Col. (Temp.) E. M. Hennessy, R.A.M.C.

M.B.E. (Military Division).—Major (Acting) H. McP. Kilgour, R.A.M.C. (since died).

M.C.—Capt. A. Crook and A. Gourevitch, R.A.M.C.

Mentioned in Dispatches.—Lieut.-Col. T. A. S. Samuel, M.C., T.D., Major (Temp.) S. W. Barber, M.B.E., and Lieut. S. T. Williamson, R.A.M.C.

The Queen of the Netherlands has conferred on Lieut.-Col. J. R. Lochead, E.D., and Major A. G. Minnes, R.A.M.C., the decoration of Officer of the Order of Orange Nassau, and on Capt. N. N. Levine and M. Victor, R.A.M.C., the decoration of Knight of the same Order, in recognition of distinguished services in the cause of the Allies.

CASUALTIES IN THE MEDICAL SERVICES

Officially presumed to have lost his life in action at sea on September 13, 1944.—Capt. George Ferguson Allan, M.B., Ch.B., R.A.M.C.

Medical Notes in Parliament

Rickets

Dr. STEPHEN TAYLOR raised, on Feb. 11, the subject of rickets. He said it differed from most human ailments in that medical knowledge of it was practically complete. Its cause was known, as also how to prevent it. The Ministry of Health Survey on Rickets, published in March, 1944, covered the whole country and had been made for the Ministry by the British Paediatric Association. By x-ray tests it was found that about 4% of the children under 18 months had or had had rickets. By ordinary direct medical examination the figure was about 12%, varying from 0% in St. Albans to 60% in Sheffield. From the x-ray figure the House must conclude that about 24,000 children suffered from rickets each year, though the figure might have changed a little since the issue by the Ministry of Food of whole-cream dried milk with vitamin D added to it. During the war the policy of the Ministry of Food had been to make vitamin D, cheap or free. Orange juice containing vitamin C and cod-liver oil containing vitamins A and D, had been chosen media, but had not been entirely successful. In a wartime social survey in April, 1944, the Ministry of Food found that among 900 mothers with young children about 70% collected orange juice and only 40% cod-liver oil. Cod-liver oil was relatively unpopular. Its consumption among children over 1 year in age fell off rapidly, while babies were liable to spit it out. Cod-liver oil and malt would not prevent rickets unless it had vitamin D added to it. He urged the Government to test a real alternative in one or two Northern towns—1/10 milligramme of calciferol dissolved in about 15 milligrammes of bland arachis oil. That mixed perfectly and tastelessly with cocoa butter. A small penny bar of chocolate taken once a week would then contain all that was needed to prevent rickets. It might be able to add to the chocolate pro-vitamin A (carotene).

Mr. KEY, replying for the Ministry of Health, said findings differed widely when, during the investigations of 1944, the same group of children were examined by several clinical observers and radiologists. Evidence of mild rickets was found in 24% of children under 6 months and about 4% of children under 12 months, with a negligible number above that age. There had been no increase of rickets during the war. The Medical Subcommittee of the Ministry's Advisory Committee on Mothers and Young Children made recommendations arising out of the 1944 report. Those recommendations were accepted by the Minister and acted upon. National cod-liver oil with its 700 or 800 units of vitamin D per teaspoonful had received publicity. Vitamin D was being added to national dried milk. There had not been a substantial increase in the uptake of cod-liver oil. Some 25% of mothers with children under the age of 5 were taking their share. Consumption seemed to be smaller in summer than in winter. Investigation showed that palatability was largely due to the way in which cod-liver oil was given to the child. Difficulty in getting the necessary quantities of vitamin A prevented the use of vitaminized chocolate. Infants would not be properly treated if this chocolate was used. Experiment in co-operation with the Ministry of Food was proceeding on the problem.

Social Research

Dr. STEPHEN TAYLOR asked on Feb. 14 if the Government would establish a Social Research Council on similar lines to the Medical Research Council. Mr. HERBERT MORRISON said the committee under the chairmanship of Sir John Clapham which, at the request of Mr. Dalton and himself, was examining the adequacy of the existing provision for research into economic and social questions, had given attention to this point. He preferred to await any observations on it that might be made in their report before reaching any conclusion.

Infectious Disease in Pregnancy

Mr. HERBERT MORRISON announced on Feb. 13 that the Medical Research Council had received reports from Australia suggesting that certain congenital defects in children, including deafness, may be causally connected with infectious disease in the mother during pregnancy. The council was investigating the subject, and the question of the effect on the child's hearing was receiving special attention.

Duty on X-ray Apparatus

Replying for the Board of Trade on Feb. 14 Mr. BELCHER told Col. Stoddart-Scott that there was a shortage of deep x-ray therapy apparatus in this country, particularly of certain components. If an application for exemption from duty in a particular case was made to the Board of Trade it would

consider carefully whether it could recommend the Chancellor of the Exchequer to grant the exemption.

Release from the R.A.F.

Answering on Feb. 20 inquiries by Col. Stoddart-Scott and Mr. Garry Allighan Mr. JOHN STRACHEY said medical officers in the R.A.F. in Groups 28 and 29 would be released in March. General duty medical officers in the Army were now being released up to Group 38 and their colleagues in the Naval medical service would be released up to Group 47 by the end of March. Distribution of recruits to the three medical services was still under consideration, but the Air Ministry hoped to receive an allocation which would help to even up the release rate.

Colonial Medical Service in West Africa

Mr. LIPSON asked on Feb. 20 what steps were being taken to recruit and train doctors for the Colonial Medical Service in West Africa and to maintain it at its present level. Mr. GEORGE HALL said applications received from qualified men for appointment to the Colonial Medical Service now nearly equalled the total number of vacancies. Applications continue to come in at a steady rate. He was concerned at the disinclination of many candidates to serve in West Africa. He had under consideration proposals designed to make the service more attractive, particularly to candidates with higher qualifications. For training the fullest use was made of the courses in tropical medicine at the Universities of London, Edinburgh, and Liverpool.

Supply of Medical Textbooks

Mr. PALMER on Feb. 21 asked the Minister of Education if she would take steps to improve the supply of textbooks for medical students. Miss WILKINSON said production of textbooks was in the hands of the publishers, but supplies were affected by shortages of labour and materials. Recent increases in the quota of paper allowed for books and the release of printers under the Class B scheme would result in better supplies becoming available soon. Where shortage of paper held up production the publishers of textbooks had an additional source of supply from the reserve held by the Moberly Committee, who were ready to give sympathetic consideration to applications for important books which the publishers could not produce from their ordinary quota.

D.D.T. in Common Use

Mr. BEVAN on Feb. 21 told Mr. Austin that according to present knowledge there was little risk attaching to the use of D.D.T. in the form in which it was commonly used—namely, as a powder or a watery suspension. Further investigations were proceeding into the toxicity of D.D.T. in oily solution. In any form D.D.T. should be kept away from food, since taken internally it was harmful.

Tuberculosis Treatment in Switzerland

Mr. E. BEVIN announced on Feb. 20 that possible arrangements for the treatment in Switzerland of a certain number of tuberculosis cases were under consideration by the Minister of Health and the Minister of Pensions, as a result of a generous offer recently made to the Minister of Health through the Swiss Minister. A proposal to take over in Switzerland two sanatoria owned by the German Government would require careful consideration from many points of view.

Psychiatric Treatment of the Prisoner.—Mr. EDE stated on Feb. 7 that arrangements existed under which any prisoner, man or woman, at any establishment could receive psychiatric treatment if the medical officer considered it desirable. He said that not all sexual offenders were suitable subjects for psychiatric treatment, but all were specially examined with a view to such treatment if the examination showed they were likely to benefit thereby.

Priority Telephone Calls for Doctors.—Mrs. MIDDLETON on Feb. 21 asked the Assistant Postmaster-General to introduce priority telephone calls for the medical profession to obviate delays in securing hospital beds for patients. She recalled that a similar system operated formerly under the National Telephone Company. Mr. BURKE replied that when a member of the medical profession had to make a vitally urgent call the operator would give the call priority if the urgency was explained at the time.

Notes in Brief

Mr. Isaacs told Sir Henry Morris-Jones on Jan. 24 that it was no longer possible to direct women to fill domestic vacancies in hospitals. He hoped that as a result of acceptance by hospital authorities of the new code of conditions relating to hospital domestic workers unemployed women would show increasing willingness to enter this field.

The Government has taken no decision to advance the next census, which is due in 1951.

Mr. Barnes repeated on Jan. 28 a previous refusal to add doctors to the list of priority categories for the purchase of Service reconditioned motor cars.

Universities and Colleges

McGILL UNIVERSITY, MONTREAL

New Department of Anaesthesia

Recently at McGill University there has been created a Department of Anaesthesia, with Dr. Wesley Bourne as its head. The chief objects are: (1) The improvement of the teaching of anaesthesia to the undergraduate student in medicine. (2) The enhancement of opportunities for learning anaesthesia by the internes of the hospitals connected with the university. (3) The maintaining of a three-year diploma course in anaesthesia for those graduates in medicine who desire to become specialists in a complete manner. (4) The development of investigation in anaesthesia, in the way of interrelationship, in the clinic and in the laboratory, and, also, in an interdependent fashion with McGill University's other departments. Dr. Wesley Bourne and his associates feel, with good reason, that the founding of their department celebrates the centenary of anaesthesia in a most practical way.

UNIVERSITY OF LONDON

Prof. Wilson Smith, M.D., has been appointed to the university chair of bacteriology tenable at University College Hospital Medical School. Since 1939 he has been professor of bacteriology in the University of Sheffield.

The degree of D.Sc. has been conferred on N. F. MacLagan, an internal student at Middlesex Hospital Medical School.

LONDON HOSPITAL MEDICAL COLLEGE

The following entrance scholarships for 1946 are announced: *Two open Scholarships* (value £100 each), in two or more of the following subjects—human morphology and embryology, physiology and pharmacology, biochemistry, and pathology, bacteriology, and morbid anatomy. The examination will be held on April 16 and 17. *Price Scholarship (Medical)* (value £100), and *Francis Farmer Scholarship (Dental)* (value £50), in biology, chemistry, and physics. The examination will be held on April 17. *Price University Scholarship* (value £100) in anatomy and physiology (limited to students of the Universities of Oxford and Cambridge). The examination will be held on July 5. Applications for admission should be sent to the Dean, Dr. A. E. Clark-Kennedy, London Hospital Medical College, Turner Street, E.1.

The Glanfield Harris Prize in Anaesthetics (value £60) is provided out of interest on a sum of money subscribed by relatives and friends in memory of Dr. John Richard Glanfield Harris, formerly assistant anaesthetist and assistant instructor in anaesthetics to the London Hospital, and will be awarded triennially to the author of the best essay on "Recent Advances in Anaesthesia." Candidates must be students of the London Hospital within ten years of obtaining a registrable medical qualification. No person will be eligible for the prize on more than one occasion. Essays for the prize will be received up to Dec. 31, 1947, and should be addressed to the Dean of the Medical College, from whom further particulars may be obtained.

Medical News

A clinical meeting of the Medical Society of the L.C.C. Service will be held on Wednesday, March 6, at 2.30 p.m., at Bethnal Green Hospital, Cambridge Road, E., when the staffs of Bethnal Green and Hackney Hospitals will demonstrate cases.

The 166th anniversary dinner of the Medical Society of London will be held at Claridge's Hotel on Friday, March 8, at 7 for 7.30 p.m. Applications should be sent to the Registrar of the Society, 11, Chandos Street, W.1.

It is hoped to institute a course of lectures and demonstrations in applied anatomy, physiology, and physics, suitable for medical men intending to take Part I of the Diploma of Physical Medicine, beginning on Monday, March 18. Prospective candidates should communicate with the Dean of the Medical School, Guy's Hospital, S.E.

The Ophthalmological Society of the United Kingdom will hold its annual congress on Thursday and Friday, May 30 and 31, and Saturday, June 1, at the house of the Royal Society of Medicine, 1, Wimpole Street, W. The subject for discussion is ocular disturbances associated with malnutrition. The president's address bears the title "Johannes Evangelista Purkinje." The Bowman Lecture will be given by Dr. Arnold Knapp, on intracapsular extraction of cataract. Part of the Friday afternoon session will be devoted to a joint clinical meeting with the Ophthalmological Section of the R.S.M. Members who intend to take part in the discussion or to read papers should write before the end of March to the honorary secretary, Mr. Frank W. Law, 36, Devonshire Place, W.1.

A meeting of the Association of Industrial Medical Officers will be held on Friday, March 22, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C. Private business will start at 4.30 p.m. and will be followed by the public business at 6 p.m. Dr. Beards will read a paper on "A System for the Recording of Sickness Absence in Industry with the Object of Determining Occupational Factors of Causation" and Dr. Chard will read a paper on "Practical Treatment of Minor Industrial Injuries". The meeting will be continued from 10 a.m. to 12.30 p.m. on March 23 at the out-patient department of the West London Hospital, Hammer Smith W. Dr. W. S. C. Copeman has arranged a practical demonstration on "Rheumatism in Industry".

The American Ambulance in Great Britain, which is being wound up after very valuable war service, has given £25,000 from its surplus funds to the Middlesex Hospital. The money will be used to endow two single bed wards, to which members of the staff of the American Embassy and other citizens of the U.S.A. will have first claim. On Feb. 20, in the board room of the hospital, Mr. Gubert H. Carr handed the cheque to Col. J. J. Astor, chairman of the board of management, who gave thanks for this gift and handed to Mr. Carr a written acknowledgment in which were set out the purposes to which the money will be applied. Others, he said, had already expressed the nation's thanks for the magnificent work of the American Ambulance. Sir Gordon Gordon-Taylor, in a tribute to the work of the American organization in the war, said that when the Royal College of Surgeons was badly damaged by enemy action in 1941, and the Hunterian Museum almost destroyed, the American Ambulance came to their aid with 78 ambulances and removed 26,000 specimens to various parts of the country. The American Ambulance Unit has also presented £5,000 to Guy's Hospital to endow four beds and two cots and the same sum to St. George's Hospital and to the Westminster Hospital.

The National Collection of Pathological Specimens of War Injuries has been moved and is now housed at Farm Laboratory, the Ridgeway, Mill Hill, London, N.W.7 (telephone, Mill Hill 1182).

Dr. Robert C. Page, a medical officer in the Army Air Forces during the war and assistant medical director of the Standard Oil Company (New Jersey), has been appointed general medical director of the company. He succeeds Dr. Willard J. Denno, chief medical officer since 1918, who developed the medical department from an office with one part-time physician to a world-wide organization having 11 hospitals and more than 150 physicians.

EPIDEMIOLOGICAL NOTES

Discussion of Table

The *Empress of Australia* arrived at Liverpool with one of the crew suffering from smallpox, three other cases had been put ashore at Suez. The infection was believed to have originated in Bombay.

In *England and Wales* the notifications of dysentery were 70 fewer than in the preceding week, while scarlet fever and measles were more prevalent, increases of 54 and 44, respectively, being recorded. The only fluctuation of any size in the returns for scarlet fever was a rise in Lancashire of 48. The increase in measles was mainly contributed by Lancashire and Norfolk (25 and 23 more cases). There were no variations of note in the local trends of diphtheria and whooping-cough.

The fall in dysentery was due to a decrease in the outbreak in Leicestershire, where the notifications fell from 130 to 69, in the preceding six weeks 797 cases were reported in this county. The other large returns were Lancashire 37, London 24, Northamptonshire 22, Northumberland 21, Warwickshire 17, Bedfordshire 10, Worcestershire 10.

In *Scotland* the chief features of the returns were increases of 128 in measles and 32 in diphtheria. The rise in measles was due to the large increase in Glasgow. The recent persistent high level of diphtheria is unsatisfactory, and another intensive drive for immunization of children against diphtheria is to be launched.

In *Eire* the notifications of diphtheria fell by 34, and those of measles by 27. The only notable rise was that of 24 for whooping-cough.

In *Northern Ireland* diphtheria rose from 16 to 24.

Week Ending February 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,303; whooping-cough 1,329; diphtheria 489; measles 1,489; acute pneumonia 1,387; cerebrospinal fever 73; acute poliomyelitis 9; dysentery 255; typhoid 5. Deaths from influenza in the large towns numbered 220. Four cases of smallpox, including one imported case, were notified during the week, 2 of the cases were reported from the metropolitan borough of Hampstead and 2 from Essex, Thurrock R.D.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 9.

Figures of Principal Notifiable Diseases for the week, and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland.

Figures of Births and Deaths and of Infant Mortality rate for: (a) The 126 great towns in England (administrative county) (b) London (administrative county) (c) The 13 principal towns in Eire (d) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1946					1945 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Deaths (0-1 year) Infant mortality rate (per 1,000 live births)	62	63	67	49	51	51	41	70	—	40
Deaths (excluding still births)†	6,552	1,049	837	27	18	6,564	923	828	320	210
Age-standard death rate (per 1,000 persons living)	—	—	18.4	17.6	—	—	—	18.8	20.6	—
Live births	7,382	1,106	874	418	258	7,002	712	819	340	236
Age-standard rate per 1,000 persons living	—	—	17.6	26.8	—	—	—	16.4	22.6	—
Stillbirths	231	31	33	—	—	218	19	30	—	—
Rate per 1,000 total births (including stillbirths)	—	—	7.6	—	—	—	—	3.5	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes puerperal fever for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.) TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Mediseca Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Indiscriminate Use of Sulphapyridine

Q.—*I was amused this morning by a request from a patient for sulphapyridine tablets for his cold. A chemist neighbour told me that a note was handed to him recently for "a bob's worth of sulphapyridine." Am I depriving my patients by adhering rigidly to the teaching that this drug is no good unless given in doses of 20 gr. (1.3 g.) every four hours in streptococcal pneumonia and other conditions caused by this organism?*

A.—The sulphonamides have no effect on the viruses which usually cause the common cold; hence this treatment for an uncomplicated cold is useless. Many of the bacteria which sometimes appear as secondary invaders are susceptible to them, and taking a sulphonamide may therefore prevent the persistence of the catarrh, the development of sinusitis, or even more serious complications which sometimes result from secondary bacterial infection. In patients whose colds habitually pursue such a course sulphonamide treatment may be justified; it is simply a waste of the drug to give it to every case. The small doses usually taken should be adequate for preventing infection, which is the aim of this treatment. Sulphapyridine is scarcely the drug of choice for this purpose, owing to its marked tendency to produce nausea; sulphathiazole, sulphadiazine, or sulphamezathine would be preferable. The fact that all of these have been in short supply is a strong reason for not prescribing them indiscriminately and unnecessarily for trivial ailments.

What is an Epidemic?

Q.—*Almost every time influenza appears some official says there is no epidemic. Shortly afterwards somebody cautiously refers to an "outbreak," and then, when everyone knows an epidemic is on, the word appears in official pronouncements. What is an epidemic?*

A.—Our correspondent's question is as hard to answer as the old question: When does a heap of stones, steadily diminished by taking away one stone at a time, cease to be a heap of stones? If in some populous area the monthly average number of notifications of, say, diphtheria were 9 and in a particular month 100 were notified, probably most people would say diphtheria was epidemic there. If 20 cases were notified, perhaps "prevalent" would be the word chosen rather than "epidemic." The word prevalent is to most of us less alarming than the word epidemic, hence an official preference for it. It is interesting to speculate why the word epidemic is more alarming. Perhaps we are unconsciously affected by the ancient doctrine that epidemic diseases were due to corruption of the "atmosphere." If that were true the only advice we could give would be to flee into clean air (the advice our forefathers did give). This might not be much less futile than official advice now given, but everybody would see its futility.

Exercise Tolerance in Valvular Disease

Q.—*Are exercise tolerance tests useful in assessing chronic valvular lesions?*

A.—Tests of exercise tolerance have not very much value in the assessment of chronic valvular disease. A careful history of the patient's activities and symptoms really provides more satisfactory information. It must be remembered that people with chronic valvular disease may have a perfectly good exercise tolerance; and people may have a bad exercise tolerance for reasons other than those connected with valvular disease. The test must, of course, be suited to the age, weight, and fitness of the patient, and to the severity of the lesion from which he is suffering.

A simple test is to record the patient's heart rate when lying, then note it when standing, and then get him to mount some twenty times or less, as thought suitable, on to a stool about 12 to 18 inches (30 to 45 cm.) high. This exertion should be carried out steadily for about 45 to 60 seconds. The heart rate can then be recorded at the end of the test, and again after one minute. Further observa-

tions can be taken at the end of succeeding minutes. In a healthy person the normal reaction would mean the resumption of the original standing rate after about 45 to 60 seconds.

Excitement may introduce a factor tending to provoke acceleration. Effort syndrome may be present, quite apart from valvular disease, and so give a defective result. Probably as important as anything else is observation of the severity and duration of any dyspnoea that may have been produced. With so many variable factors, it is obvious that the test must be considered in the light of other findings. It has, however, a definite place where information of an objective character is desired as to the effect of physical exertion upon the heart. Most textbooks have information on the subject.

Pasteurization and Surgical Tuberculosis

Q.—*Are there any statistics available which prove that pasteurization of milk results in a fall in incidence of surgical tuberculosis. If so, what are the relevant facts?*

A.—Statistics which prove that pasteurization has decreased the incidence of surgical tuberculosis are not available. Deaths from tuberculosis, except for the country as a whole, are tabulated under two headings only—"respiratory tuberculosis" and "all other forms." The trend of the mortality from surgical tuberculosis must therefore, be indirectly estimated from "all other forms." This indirect approach was made by Prof. G. S. Wilson in his book *The Pasteurization of Milk* (Arnold, London). He compared the experience of London, where almost 100% of the milk is pasteurized and that of the rural districts, where most of the milk consumed is raw. While not proving in a strictly scientific sense that pasteurization has decreased the incidence of bovine tuberculosis, the evidence produced supports this contention.

Internal Combustion and Vitamin B

Q.—*I read in the "New Statesman and Nation" that recent discoveries in the vitamin B group show that they "quicken the processes of internal combustion, so that the desirable loss of heat takes place easily and a man can remain energetic and mentally alert without succumbing to the lassitude which a hot climate usually imposes." How much of the above statement is true?*

A.—As so often happens, the superficial analogy of the human body with an internal combustion engine, implied in the question is very misleading. There seems to be some confusion between "loss of heat" and the stepwise release of energy, due to a chain of enzyme reactions, that results finally in the complete combustion of carbohydrate (glucose) to carbon dioxide and water. Several of these reactions are catalysed by enzymes, of which certain water-soluble vitamins form an integral part; these are aneurine (thiamin, vitamin B₁), riboflavin, and nicotinic acid (or its amide). It is doubtful whether there have been any serious scientific publications showing that these processes, provided they are proceeding normally in a healthy body receiving an adequate diet, can be at all influenced in such a manner as to affect the heat-regulating mechanism of the body.

Difficult Child

Q.—*While I was away from home my daughter, aged 3½, fretted for me, would ask after me at meal-times, and be sick. I have now returned home, but the trouble continues. She still creates a scene at meal-times, saying first that she has cramp, then that she is hungry and wants feeding, and then she is sick. After that she generally eats well. She declares that it is her naughty dollies who are sick and who make her miserable. What is the right treatment?*

A.—Feeding difficulties are very common between 3 and 4 years of age, and usually clear up spontaneously unless too much notice is taken of them. In this case the onset of symptoms while she was missing the parent, and her insistence on projecting her "naughtiness" on to the dollies, suggest that she is suffering from anxiety so acute that she cannot control her behaviour. It would probably be wise to let her be seen by a children's psychiatrist, but if there is a good day nursery or nursery school in the neighbourhood it might help her to attend this. Feeding difficulties often cease when children have meals in a group, and the nursery should be able to provide additional outlets in play and other occupations that would benefit her considerably.

Altered Blood from the Nipples

Q.—*A woman of 50 has noticed for some months that on squeezing the nipples a small droplet of an inky-black fluid can be expressed. There is no pain, and the breasts and the nipples look quite healthy. What are the cause of this, and the treatment?*

A.—The discharge from the nipple in this case is almost certainly old changed blood arising from small papillomata in the larger sub areolar collecting ducts. If the sector of the breast radiating from the particular point at which the discharge appears is palpated, it will probably be found that pressure will produce more discharge. Some of these papillomata in the course of time may undergo malignant change into duct carcinomata, but others have been

followed for many years without any sign of such change. It is sometimes advocated that the small sector of the breast concerned should be excised, but this may be followed by a repetition of the discharge from other sectors. On the whole it is probably wisest to do nothing active at this age, although the breast must, of course, be kept under active observation. The writer has not seen much improvement following x-ray treatment in these cases, and mastectomy (in this case bilateral), which has been suggested, would appear rather too drastic a treatment for a condition which is, after all, only potentially malignant.

Seborrhoeic Dermatitis in a Child

Q.—What is the best treatment for seborrhoeic dermatitis in a child of 1 year? Is the diet of any importance? If sulphur is used is there a risk of producing a sulphur dermatitis?

A.—External treatment by sulphur requires experience and judgment, and is perhaps best avoided except in conditions such as acne and rosacea where the seborrhoeic basis requires it. This applies to all forms of infantile eczema, because, although it is sometimes effective in the seborrhoeic variety, the chance of aggravation is not inconsiderable. Probably a mild boric and zinc ointment with 2% ichthammol would prove a safer application.

Diet in infantile eczema is a controversial subject, and while skin-tests often prove positive to such things as egg-white and milk, their exclusion usually makes no difference to the eruption. The fat over-nourished child probably benefits from restrictions, but at the present time special diets are either difficult or impossible, and might even interfere with the development of a growing child.

Abortion

Q.—A woman aged 30 had an abortion (2 months) in 1943. In December, 1945, she gave birth to a five-months foetus. From her history the pregnancy should have been seven months, but the foetus was in good condition and did not look as if it had been dead for two months. A week before labour she had a slight haemorrhage, and just after it a rather more pronounced one. Can you tell me: (1) the most probable cause or causes; (2) the chances of a future normal pregnancy; (3) the best immediate post-natal treatment; and (4) if she attempts a future pregnancy what precautions should be taken? She has a slight degree of anaemia and is rather nervous; otherwise normal.

A.—(1) The fact that the foetus was small for its age rather suggests some interference with its nutrition and possibly an underlying fault in the placenta. It would be interesting to know whether the latter showed signs of infarction or other abnormality. Steps should be taken to exclude vasculo-renal disease—of which even a slight degree may be significant—and any general illness which might impair foetal nutrition. The anaemia may be important, and its nature and degree should be determined. The mention of nervousness raises the possibility of thyrotoxicosis as a causal factor in the abortions. Local disorders should also be looked for, and if bimanual examination gives negative results uterolappingography could be carried out, to exclude deformities such as a septate uterus. If no cause can be found it should be remembered that the occurrence of two abortions is not necessarily indicative of an abortion habit; they may each have been caused by random factors not likely to recur.

(2) The chances for the future depend largely on the cause of the abortions, if one can be found. For all cases of two consecutive abortions, however, and irrespective of treatment, it has been calculated mathematically that the chances of the third pregnancy progressing to term are 30 to 60% (for full discussion see P. Malpas, *J. Obstet. Gynaec. Brit. Emp.*, 1942, 49, 65). If a cause can be found and treated the chances are, of course, much higher.

(3) There seems no need for immediate treatment other than for the anaemia and any other condition which investigation brings to light.

(4) Advise the patient to wait six months from the time of the last abortion before attempting to conceive again. In the next pregnancy, if no cause for the abortions has been found, treatment should be on the usual empirical lines: rest, avoidance of coitus and travelling, sedatives for general nervousness, and possibly twice-weekly injections of 5 mg. progesterone up to the twenty-eighth week of pregnancy. Attention should be paid to ensuring the patient an adequate diet; supplements of iron and large doses of vitamin E might be helpful.

Menopausal Neuralgia or Rhinitis

Q.—About 30 years ago a lady had severe influenza followed by frontal sinusitis, which was treated surgically. Recently she has had neuralgic attacks in the distribution of the right fifth nerve; the eye waters and becomes slightly congested. A.P.C. tablets do good temporarily, and I have used the ordinary type of nasal spray, keeping the mouth open during this procedure. Would a course of sulphonamides or penicillin be useful?

A.—Before advising treatment an attempt at a more accurate diagnosis should be made. The symptoms given in this question

correspond more closely with trigeminal neuralgia or menopausal vasomotor rhinitis than with frontal sinusitis. If there are no facilities for diagnosis other than observing the effects of treatment, ephedrine 1/2 gr. (32 mg.) and phenobarbitone 1/2 gr. (32 mg.), twice daily, with an adequate dose of stilbestrol, are effective in controlling the symptoms of vasomotor rhinitis. Neither penicillin nor sulphonamides are indicated without more adequate investigation of the cause of the pain.

INCOME TAX

Assistant Installed in Own Residence

B. C. has hitherto been allowed to deduct only one-half of the expenditure on house rent, rates, heating and lighting, and cost of maid. He has now installed a full-time assistant in the house and has left the district.

* The whole of these expenses are claimable as from the date when B. C. ceased to use the premises as a private residence. The benefit which the assistant receives by residing on the premises provided at B. C.'s expense is not part of the taxable income of the assistant.

Use of Car

H. J. is in full-time employment, and receives £45 per annum plus 34d. per mile for the use of his car. He proposes to sell the car for, say, £350, and buy another for, say, £500. What relief, if any, can he claim against his income-tax assessment?

* In ordinary circumstances the Revenue authorities would not entertain such a claim, holding that the cash received would, over a period of years, cover the "necessary" cost of travelling in the performance of the duties. It is possible that representations that in existing conditions the cost of replacement is quite abnormal and therefore has not been recouped might succeed to the extent of securing deduction of some part of the £150 to be expended in replacement.

M. N. has a "full-time Government appointment," but is allowed to do a little private practice in his spare time. He keeps a car but receives no allowance for its use in connexion with his appointment. What can he claim for its use against his earnings from private practice?

* A proportion of the total running costs, including depreciation, insurance, etc. The proportion will presumably be determined by the ratio of the total mileage to the mileage specifically due to the private practice. If the result of the private work is that a loss is incurred, the amount can be set against the Government salary, etc., under Section 34 of the Income Tax Act, 1918.

Temporary Residence in the United Kingdom

E. J. holds a Colonial appointment and has been granted twelve months' special leave for a specified form of training. He will continue to pay the Colonial tax. He landed in this country on Oct. 31, 1945. What is his liability, if any, to British income tax?

* E. J. has clearly come to this country for a temporary purpose only and without the intention of establishing a residence here. Accordingly he will not be liable to British tax in respect of his Colonial income unless he spends six months in this country in any one financial year. As he did not arrive until Oct. 31, 1945, he will not be liable for the year to April 5, 1946; and he will not be liable for the year to April 5, 1947, unless he spends six months in this country in that year.

"GASIMA" is in the Colonial Medical Service and has been granted three years' study-leave in this country.

* He will apparently become "resident" but not "ordinarily resident" and will be liable to British tax. He will, however, be entitled to "double income tax" relief, and to the usual allowances—i.e., £180 for a married man and £50 for each child, and 10% in respect of earned income. Fees paid for medical courses and examinations will not be deductible.

Deduction of Tax from Assistant

R. R. explains that a former assistant of his acted as his locum-tenent while on Army leave. He has asked the local inspector of taxes what tax he should deduct but has had no reply.

* As the former assistant is not normally carrying on his profession as a locum-tenent it seems to be both right and desirable that he should be treated as an employee and suffer tax by deduction. The amount to be deducted is the sum shown against the appropriate amount of "gross pay" on the pink "emergency card." If R. R. has not been supplied by the tax office with such a card, no doubt he will receive one on a request being made.

LETTERS, NOTES, ETC.

Longevity

Dr. HUGH MACKINTOSH (Troon) writes: Your correspondents appear to have overlooked two rather important indicators concerning longevity. First, human remains have been disinterred by archaeologists, almost certainly pre-Flood, having characteristics that indicate longevity far greater than anything we can at present conceive. The most striking indication is the extraordinary way in which the teeth are worn right down into their sockets by long usage. Thus "the ancient cemetery at Ur (i.e., Abraham's Ur of the Chaldees), and the still more ancient one (circa 2,000 years older) at the neighbouring site called Al-Ubaid, testify strongly not only against revolutionary theories but also to the accuracy of the Bible in ascribing long life-periods to primeval mankind." And Sir Arthur Keith states: "Certainly, as physical anthropologists measure people, the later people of Ur were not the equal of the earlier people found at Al-Ubaid"; and again: "The ancient Sumerians were a large-headed, large-brained people, approaching or exceeding in these respects the longer-headed races of Europe. . . . The teeth of the early Sumerians of the Al-Ubaid cemetery were worn down to an extraordinary degree—much more than those of the people buried in the later cemetery of Ur itself." Actually there is ample secular evidence to show that there once existed on this earth of ours a race of men of magnificent physique, splendidly muscled, with a brain capacity exceeding that of modern man, and having all the signs of extreme longevity. My second point is that in trying to estimate the claims of the Bible for great length of years your correspondents are assuming that climatic conditions on the earth have always been as they are now, whereas there is much evidence that that is not so. In his book *Evolutionary Geology* McCreadie Price shows that the geological evidence supports the view that at one time the earth enjoyed a uniformly warm climate from pole to pole ideally suited for the growth and long life of plants and animals. The plants and animals that existed then and whose species have survived to the present day were giants of their kind. He also shows that a catastrophe of world-wide character occurred that could only be explained by the Flood of the Bible. There is only one thing that can be visualized as giving a uniformly warm and equable climate—namely, something that would envelop the whole earth so as to prevent the direct rays of the sun from penetrating its surface and at the same time act as a heat-trap. The only thing that can be imagined as doing this is a complete envelope of water vapour high up in the atmosphere or at its upper limit. Under such conditions the climate would be uniformly warm, with no extremes of any kind, and there would be no showers but a heavy dew to water the surface of the earth. Nor would the seasons exist as they do now, nor the clear distinction between day and night that a direct view of the sun, moon, and stars gives. If, by some chance cause, this belt or envelope of water vapour were to be precipitated on to the earth, the result would be a flood of the extent described in the Bible, with all those extremes of heat and cold, moisture and drought, that we now experience due to the action of the direct rays of the sun. So it would seem that conditions for animal and plant growth and survival were once much more ideal than they are now, and that we cannot judge the possibility of the extreme longevity claimed in the Bible on the assumption that climatic conditions were the same then as they are now.

Jittery Legs

A. R. writes: The following two personal cases suggest that this symptom, which was discussed in the annotation (Jan. 19, p. 95), has a sexual basis. (1) For some years I was troubled with pruritus. If the scrotal skin around the root of the penis was traumatized—e.g., by too rough drying after a bath or by scratching—I invariably had symptoms in bed shortly after. Trauma to the under surface of the scrotum or to the perineum had no such sequel. The symptoms were similar to those you describe, and consisted of an ill-localized discomfort, apparently in the muscles of the calf, relieved for some 5 to 10 seconds by movement of the legs, then building up again and demanding another movement for its relief. This happened only in bed. Until I discovered a means of speedy relief the symptoms would persist for some half to one hour on each occasion. I found that a local anaesthetic applied to the traumatized area usually gave prompt and complete relief. Occasionally, if the trauma had been more severe, relief was only partial. (2) During the first years of our marriage my wife sometimes had similar symptoms when lying close to me in bed. These were relieved either by coitus or by moving further apart.

"General Debility"

Dr. H. CRICHTON-MILLER (Harrow-on-the-Hill) writes: On p. 303 of the *Journal* of Feb. 23 a question is asked in the following terms: "How can so-called general debility in the ordinary working-class patient be tackled so as to get the quickest recovery?" Without

commenting on the positive advice offered, may I enter a protest what is omitted? I refer to the complete absence of any reference to bacteriogenic conditions. Not a word is said about septic toxæmia or intestinal stasis; no mention is made of infected sinuses or dental toxæmia. And yet these must account for a goodly proportion of cases. May I suggest that before prescribing a "large amount" of rest or exhibiting an equally "large amount" of appreciation the practitioner would do well to investigate the E.S.R.?

Descent of the Testis

Dr. H. MACNAUGHTON-JONES (Amersham) writes: There is a simple explanation which may account for the descent of the testicle at birth which does not appear to have been mentioned. The season in which birth took place was a material consideration in non-migratory animals, including man during his development and in primitive states before the adoption of clothes. Though the increased survival of the young born at a particular period would, apparently, be sufficient to secure parturition during it, in animals in which there was a material interval between copulation and parturition the exposure of the testicle to climatic changes would be a valuable factor in determining the presence of minimum and maximum appetence in the male at the appropriate times. Indirectly and to a minor extent it would affect the period of appetence in the female, inasmuch as those in which its presence coincided with that in males would be those most frequently bearing young, and during development would lead to correlation.

Hypodermic Needle for Skin Suture

L./S.B.A. KILLE (Glenholt Camp, Plymouth) writes: The other day an incised wound of the wrist was sutured in a way I had never seen before. All the S.B.C.P.O. used was a hypodermic needle and horse-hair suture, prepared with the usual aseptic precautions. The suture was passed through the bore of the needle till the end was visible but clear of the needle point. With his free hand he brought together the wound edges, and with a smooth sweep passed the needle through the flesh on either side of the wound; the patient was unaware that he had been touched with a needle. The suture was passed on through the bore and the end gripped with the free hand; the needle was then withdrawn along the length of the suture, and the suture was tied. Four sutures were inserted in this way without any discomfort to the patient, and the operation was as neat as any I have ever seen.

Toxic Effects of High Octane Petrol

Major JOHN H. LANKESTER, R.A.M.C., writes from Oxted: With reference to the question and answer under this heading (*Journal* Jan. 26, p. 152) and to Mrs. Jean Patey's note (Feb. 16, p. 264) some of the patient's symptoms may well be caused by the tetra-ethyl lead which is added to high octane petrol. Intoxication by the tetra-ethyl lead contained in 100-octane petrol was common among Indian Pioneers engaged in filling petrol cans in Abadan in 1943-4. Three or four deaths occurred before adequate preventive measures could be adopted. Absorption of this form of lead is largely by inhalation, and is accelerated by high temperature. The severe cases with mental symptoms were during the excessively hot summer months. Early symptoms include headache, giddiness, epigastric discomfort, and muscular weakness. Later, and often with dramatic suddenness, mental symptoms supervened in the form of violent mania with acute terror. Such cases were usually fatal. Preventive measures adopted were: improved ventilation at working site, reduction of spilling, the use of a barrier cream on the hands, and the strict enforcement of a roster of duty which gave operators other duties away from exposure to petrol in order to allow excretion to take place. Special precautions are also necessary in the handling of the pure tetra-ethyl lead. An authoritative article by the medical staff of the oil company concerned would be of interest.

Service Conditions and the Ethical Code

The writer of the letter with this heading published on Jan. 12 1946 (p. 76) under the pseudonym "Hippocrates" informs us that the dental surgeon in question was not an officer of the Army Dental Corps.

Medical Golf

The Medical Golfing Society marked its renewal of activities by a dinner at the Trocadero, in conjunction with its annual general meeting. Sir Charles Gordon-Watson was in the chair. Some 41 members were present, and all enjoyed a good dinner and a very cheery evening. It is hoped to hold a one-day meeting at Walton Heath, and in the late autumn a week-end meeting at the sea.

New Year Honours

Acting Squad. Ldr. Frank Desmond MacCarthy, R.A.F.V.R., was appointed O.B.E. (Military Division) in the Honours List published on Jan. 1.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 9 1946

THE HEALTH OF INDIA*

BY

Sir JOHN MEGAW, K.C.L.E., D.Sc., M.B.

Major-General, I.M.S.(ret.), President, India Office Medical Board, and Medical Adviser to the Secretary of State for India, 1933-9

For more than 25 years I have studied the health situation in India with ever-increasing anxiety and with a growing conviction that the country was heading for a calamity which could not be prevented unless the people were aroused to a sense of their danger and thereby induced to take the road to safety that is open to them.

The health of India is a vast and complicated problem, but, like many other great problems, it will be found simple in its essential aspects if examined in the right way, which is to make a search for the basic principles concerned, and to refuse to allow one's attention to be distracted by side issues. When this method of inquiry is adopted it becomes clear that the health of human beings throughout the world is governed by certain natural laws which are so obvious that an apology would be needed for stating them if it were not that they are widely ignored.

These laws, though unwritten, have been discovered by the simple process of observing the state of health of groups of persons living in different ways in various parts of the world. It has been found that high standards of health and length of life are enjoyed by all the groups that follow a certain general plan of life, whereas ill-health and premature death are common in all the groups that fail to conform to this plan. It might be expected that differences of race and climate would have a disturbing influence on this observation, but these and other factors can be ignored, because it has been found that the better standards have always been achieved irrespective of all such considerations when the rules of healthy living have been adopted.

The Basic Law of Health

The basic law of health can be stated either as a command with a promise attached or as an article of a penal code. Expressed in the former way it would read: "Every community in which effective action has been taken to control all the diseases that can be prevented will be rewarded by a high standard of health and longevity." Stated in the other way the law would run like this: "Failure on the part of a community to protect itself against preventable diseases will be punished by sickness, misery, and premature death. These penalties are inflicted without mercy and in an indiscriminate manner on men, women, and children of the offending communities." The obvious is often overlooked, and this matter is so important that it deserves to be closely examined to make sure that the law just stated is clearly understood.

Malnutrition a Preventable Disease

First of all there is the question of what is meant by the term "preventable diseases." There is a general impression that the only important preventable diseases are those caused by infec-

tion, indeed, there are countries in which a high standard of health has been attained by concentrating attention almost exclusively on the control of these diseases. This success has given rise to the assumption that similar results can always be obtained by the prevention of infection, and accordingly the efforts of the public-health organizations have everywhere been directed towards this end. But there are many countries, of which India is one, where another group of diseases may be responsible for more sickness and premature death than all the infectious diseases taken together. This group consists of the types of malnutrition caused by insufficient and unsuitable food. The most casual observation of the people of any overcrowded country like India shows that most of the inhabitants suffer from lifelong ill-health and poor physical development, which are clearly due to faulty nourishment. There is also abundant evidence to show that in these countries most of the people who die prematurely of infectious diseases would have survived if their resisting powers had not been sapped by malnutrition. So that, although the official returns show one or other infectious disease as the cause of death, from the practical point of view the real cause has been malnutrition.

The means of preventing malnutrition has never been a mystery, so that in the strictest sense of the term it is a preventable disease. The real mystery connected with malnutrition is that in the countries where it is a major public-health problem no effective organizations have been set up to measure the harm that it does and to supply expert advice on the steps needed for its control.

I do not forget the valuable research work that has been done in India on the subject of nutrition; this has shown beyond any shadow of doubt that the diets of most of the people are quite inadequate to maintain health. The information made available by research ought by itself to have called attention to the need for a thorough investigation into the root causes of the inadequacy of the diets.

Rewards and Punishments

Let us see what standards of health can be obtained by complying with the basic law of health, and how these standards compare with those existing in India to-day.

It will be found that in every country in which malnutrition and infectious diseases have been reasonably well controlled the average length of life has increased to well over 55 years; indeed, it can be stated with some degree of confidence that when the knowledge already available has been fully applied to the prevention of disease an average duration of life of more than 60 years will easily be obtained. Seeing that the average length of life in India is less than half this figure, it is clear that the people are sacrificing more than half the period of existence that has been made available to them by Nature. This is not the whole story; the shortened span of life is spent in a disease-ridden and miserable condition.

* The Sir George Birdwood Memorial Lecture delivered before the India and Burma Section of the Royal Society of Arts.

The remedy, of course, is obvious. So far as infectious diseases are concerned an effort has been made in India to apply the remedy, and already an appreciable degree of success has been achieved. I do not propose to deal with the subject of *control of infection*; this aspect of the public-health problem is being tackled on sound lines, and if the results have hitherto been disappointing the reason is that malnutrition has been allowed to persist.

The control of malnutrition is a straightforward matter; perhaps, indeed, the apparent simplicity of the problem has been the reason why the help of public-health experts has not been considered necessary, except in connexion with dietetic research. It has always been assumed that the only thing needed was to produce more food. By such means as the construction of great irrigation works and the introduction of improved methods of agriculture, enough extra food has actually been provided to feed many millions of people. Great credit is due to those who have planned and carried out these schemes.

But a new, and unexpected, factor came into play; this was a prodigious increase in the rate of growth of the population, resulting from a reduction in the number of deaths from infectious diseases. By the irony of fate the public-health organization, in controlling one group of preventable diseases, has created conditions in which the control of the other group has become increasingly difficult.

The Law of Growth of Population

Clearly the adequacy of a food supply depends not only on the amount that is available; the number of mouths to be fed must also be taken into account. Now this factor in its turn is bound up with the working of a law of Nature which is of basic importance in connexion with the prevention of disease, and which, like the basic law of health, has been discovered by the simple and reliable method of observing what happens among different groups of human beings all over the world. It may be called "The Law of Growth of Population," and it can be stated in these words:

"When a community of human beings is completely protected from premature death caused by preventable diseases and violence, its numbers increase so rapidly that they become doubled and redoubled every 25 to 30 years unless some check is imposed on the natural rate of reproduction."

The conditions in which this maximum rate of increase occurs are very rarely complied with in every respect; no country has yet completely abolished all the preventable diseases, and those countries in which this goal has nearly been reached have almost invariably imposed checks on the birth rate by such methods as celibacy, delayed marriage, and the use of contraceptives, so that we cannot expect to find large-scale examples of the rate of increase just stated. But if we look at the communities in which no checks are imposed on the natural birth rate and in which good standards of nutrition prevail, it will be found that this rate of increase is more and more closely approached according to the degree to which deaths from infectious diseases are prevented.

A striking example of increase of population was given by Sir Evelyn Wrench in the *Times* of March 1, 1938. This writer stated that the 60 000 Frenchmen who settled in Canada in 1859 had nearly 5,000 000 descendants alive in 1938. Making allowance for preventable deaths from infection and the checks imposed by celibacy and delayed marriage it seems certain that the capacity for multiplication must have been at least as great as that stated in the law.

Some experts have raised objections to the validity of this law and have argued that when a good standard of health and comfort has been achieved the birth rate automatically declines. But their arguments are based on what happens in countries where the number of births are restricted in the ways already mentioned. It is now generally recognized that in these countries the striking fall in the birth rate has been due to various controls deliberately applied with the object of achieving the desired standard of living. There is no evidence to support the inherently improbable theory of a sudden decline in the capacity for reproduction. In communities where contraception is practised there is no means of finding the extent to which this is responsible for causing a reduction in the number of births;

but in countries like Eire, where the population is controlled by celibacy and delayed marriage, we can see how drastically these measures have to be applied to prevent an undue rate of increase.

Anyhow, we are concerned with India, where none of the methods of birth control is practised to an appreciable degree, and here we find that the birth rate is highest in those parts of the country where food is most abundant. It would therefore be the height of folly to rely on a comforting theory based on no reliable evidence and flatly contradicted by experience in India and all other crowded countries in which the natural birth rate is unrestricted.

Now let us see the implications connected with the law of growth of population, even if the very conservative period of 30 years is adopted as the time needed for doubling to occur. In India, for example, suppose that complete success had been obtained in the prevention of infectious diseases, and suppose that adequate nourishment were provided for the existing population by increasing the available supply of food by 50%. What then would have to be done to maintain these satisfactory conditions of life if the people refused to make any change in their matrimonial customs? A further progressive increase in the food supply would be needed so as to bring this up to three times the present amount by the end of 30 years, to six times the present amount within 60 years, to 12 times that amount in 90 years, and so on.

These figures, of course, are fantastic, but they do not reduce the law of growth of population to absurdity; what they do show is the utter impossibility of achieving and maintaining good conditions of health without imposing a check on the birth rate.

The people must choose for themselves whether to adhere to the present system of unrestricted propagation of children with its attendant misery or voluntarily to apply an adequate check. If the latter alternative is chosen they must select the kind of check that they prefer; no Government can dictate in a matter of this kind, but equally no Government can be held responsible for failing to provide health and well-being to people who refuse to conform to the natural laws which must be obeyed if these blessings are to be secured.

Up to now I have been dealing with the general principles of health, with special reference to highly populated countries like India, and I hope I have made it clear that these principles are both simple and obvious. It must also be understood that they apply to all human beings, for all time, and in every part of the world. They ought to form the basis of all public-health efforts.

Let us look at some examples of the manner in which these principles or laws have been operating in India in recent times.

Growth of Population in India

Since the first census was made in 1872 the population of India has been increasing; for 50 years the rate of increase was irregular, but on the average it was about 4% every ten years. Since 1921 there has been a remarkable rise; during the ten years 1921-31 the increase was by 10%, in Travancore there was a startling rise by 27%; in the ten-year period 1931-41 the increase for the whole of India was by 15%, or an actual increase of about 50,000,000. In this period the most striking increases occurred in North-Western India, Bengal and Travancore, where they ranged from 19% to over 22%. When allowance is made for the large number of deaths from infectious diseases it is clear that in these widely separated areas the population could easily have become doubled within 30 years, provided that enough food could have been obtained and that infectious diseases could have been fully controlled.

Optimistic Views

These figures, especially the addition of 80,000,000 to the total population within 20 years, were obviously portentous; but there were differences of opinion as to what they actually did portend. On the one hand the considerable decline in the number of deaths from infectious diseases, coupled with the freedom of the country from any widespread famine, was regarded by optimists as evidence of a healthy state of affairs. For example, in 1940 a very distinguished expert claimed that

it was possible to look with considerable satisfaction on recent progress and future prospects of public health in India, he said there was good reason to expect that improvement in the standards of life would cause a decline in the birth rate.

In the recently published report for 1942 of the Public Health Commissioner it was stated that the death rate, 213 per mille was the lowest ever recorded, and that the birth rate had also fallen to 29.2 per mille—a decline of special interest in view of the discussion on "what was regarded as the increasing population pressure and the alleged failure of food supplies to keep pace with it."

In the book *Social Service in India* (1938) the following statement is made "The sting of famine has been drawn, indeed the Famine Codes published in the early years of this century are mostly obsolete and lie undusted on the office shelves."

The Bengal Famine

It appears that even in well informed circles there were some who could take a complacent view of the situation up to quite recent times. On the other hand there were ominous signs as will presently be seen but these attracted so little attention that the distressing famine in Bengal in 1943-4 caused a gasp of astonishment as well as of horror in India and in this country. The causes of the famine have been fully and ably dealt with in the report of the Commission which made a thorough investigation under the chairmanship of Sir John Woodhead. This deals chiefly with the causes that actually precipitated the famine, but to my mind the most important part of the report consists of a few sentences which describe "the background against which the events leading to the widespread starvation in 1943 must be viewed." Here are some of the most significant findings.

The Commission obtained evidence showing that about one half of the 7,500,000 families depending mainly or solely on agriculture for their livelihood held less than two acres of land or owned no land at all, whereas the smallest area needed to maintain an average family in reasonable comfort was estimated as being at least five acres. In their search for evidence to show the previous state of nutrition of the people of Bengal the Commissioners had to fall back on a survey, made by myself, of the health conditions in the villages of India in 1933. This survey was carried out by sending a list of questions to a large number of doctors working in typical agricultural villages, the doctors were asked to confine their replies to facts and opinions based on their own observations. An analysis of the replies received from 69 doctors working in different parts of Bengal showed that 22% of the people were regarded as "well nourished," 47% as "poorly nourished," and 31% as "very badly nourished."

The Commission accepted these figures as "indicating in a general way the unsatisfactory state of nutrition of the people of Bengal ten years before the famine," though they also remarked that the findings could not be accepted as showing conclusively that nutritional conditions in Bengal were worse than those of India as a whole. In my own comments on the survey the same opinion had been expressed, and I had also pointed out that while the findings were regarded as conveying a substantially true impression of conditions of rural life in British India, one of the chief objects of the survey was to show the need for a thorough investigation into the state of health of the agricultural population. It is indeed surprising that the Commissioners should have been compelled to rely on this rough and ready inquiry of the "Gallup poll" type as the only available evidence on so momentous a question.

The Commissioners went on to state that poverty and malnutrition in Bengal left a section of the population with few reserves, material or physical, to meet superimposed calamity, that there was no margin of safety, and that though such conditions were common to most other provinces of India they were of fundamental importance and were favourable to the occurrence of famine. Among the general conclusions it was stated that agricultural production was not keeping pace with the growth of population, and that a considerable section of the people were living on the margin of subsistence.

The significance of these statements is greatly enhanced by the fact that they carry the authority of a man who weighs his words with a deep sense of responsibility. It becomes clear that, although the factors responsible for precipitating the famine were largely unpredictable, there were also basic factors which, if allowed to operate without interruption, would have made famine inevitable sooner or later. It is also clear that these basic factors could have been observed, and that from an examination of the trend of events a forecast could have been

made showing that any exceptional shortage of the harvests due to failure of the rains would precipitate a crisis.

A remarkable feature of the famine was that the actual shortage of food in 1943 was estimated as being only about 6% of the normal supply. Special attention should be paid to the ominous words already quoted that the fundamentally important basic conditions were common to most other provinces of India.

The most important lesson to be learned from the famine is the need for an organization charged with the duty of providing reliable information with regard to the nutritional condition of the people, and of preparing regular forecasts based on the observed trends of population and food production, to show what is likely to happen not only in seasons of normal harvest but also in the event of widespread failure of the crops.

A curious sidelight on conditions in Bengal before the famine is contained in the Bengal Health Report for 1941, which was issued only a few weeks ago. It appears that in 1941 the death rate was 6.6% higher, and the birth rate 5.3% lower, than in 1940. This simultaneous deterioration in the death and birth rates is very unusual, it had happened in 1918, when it was accounted for by the influenza pandemic, and again in 1933. Without a careful examination of all the circumstances it would be rash to express a dogmatic opinion about the significance of the figures, but the recurrence in rapid succession in 1938 and 1941 of so exceptional a feature in the statistics suggests that the nutritional condition of the people of Bengal was approaching the critical point at which the reproductive capacity of the people begins sharply to decline.

The statistics for India as a whole show that a relatively high birth rate can be maintained in spite of low nutritional standards, so that any considerable fall in the birth rate that cannot be explained by the occurrence of severe epidemics may well be a danger signal showing that the community is coming perilously near the breaking point at which a further reduction in the food supply is likely to precipitate famine.

Distress in Travancore

Bengal was not the only part of India to suffer from distress in 1943. The Chief Minister of Travancore made a public statement in the month of October in that year to the effect that a distressing condition of under nourishment and famine conditions had existed unrelieved in the State during the previous twelve months. Eyewitnesses have given detailed reports of widespread starvation, though not on so spectacular a scale as in Bengal.

The experience of Travancore is even more instructive in some respects than that of Bengal. The State is described in the latest edition of the *Encyclopaedia Britannica* (1929) as being "conspicuous for good administration and prosperity." This remarkable tribute is universally regarded as being well deserved: the people have attained an exceptionally high standard of literacy, they are orderly, intelligent, and industrious and private philanthropic agencies are unusually active. Only a few years ago the very idea of danger of famine in the State would have been scouted.

Yet the Census Report of 1941 is quoted as stating that in the lowland agricultural areas the increasing density of population was reducing the people to "a level of sheer despondency," and that in these areas there were 1,833 to 2,407 persons on each square mile of land.

It has already been seen that the growth of population in the State has been phenomenal, in the three successive decades since 1911 the percentage increases were 168, 27.2, and 19.1. In actual figures the increase during the 20 years 1921-41 was from about 4,000,000 to 6,000,000 or about 50%.

The author of a report in which the famine is described expresses himself as being "staggered" at finding that, whereas in 1938-9 there were 200 births for every 100 deaths in 1942-3 there were only 150 births for 100 deaths. I, myself, find these figures staggering, but not for the same reasons, the author seems to regard the occurrence of two births for every death as a standard that must be maintained, but he does not appear to have asked himself the question—How long can the people continue to find food if their numbers go on increasing at this rate? I find the numbers staggering for another reason, they show that even in conditions of distress the population has continued to swell at a relatively rapid rate. Nature obviously

does not begin to exercise effective control over the inordinate rate of growth of the population till the people have been reduced to an extreme condition of misery and weakness.

The same author's plans for restoring prosperity to the State are interesting. He recommends an increase in the area under grams and pulses, the development of mixed farming, the keeping of cattle, poultry, sheep, and pigs, and, "more than all, the purchasing power of the consumer must be increased." Remedies like these are often advocated by well-meaning persons who do not appreciate the unfortunate fact that a well-balanced nutritious diet cannot be produced on an area of ground that is only large enough to provide a meagre ration of such bulky foods as tapioca or rice. To suggest a system of mixed farming for a family that has to maintain itself on a plot of less than two acres is absurd. In such conditions the people are compelled to grow the crop that gives the largest yield as the only way of staving off hunger. When animals are kept they must be fed either on the produce of the land or on food bought in the market in exchange for the money obtained by the sale of a cash crop. In either case, the milk, meat, or eggs provided by the animals would not go far to satisfy the hunger of the family. On miserably small holdings all that can be hoped for is to keep the family alive at a wretchedly low standard of nutrition.

The Government of Travancore is making an effort to increase production by the use of fertilizers, and this step is likely to ease the situation to some extent, but if the people are thereby enabled to produce two babies in exchange for every person who dies the outlook for the future is far from bright.

The experience of Travancore is fundamentally similar to that of Bengal, but there is one special lesson to be learned from Travancore; this is that a high standard of literacy, even when combined with the advantages of a humanitarian administration and private philanthropy, cannot avert the inevitable consequences of disobeying the laws of Nature.

Criticisms Forestalled

Critics will doubtless discover a weak point in arguments based on the experience of Bengal and Travancore; in both of these areas famine conditions were precipitated by the sudden cessation of rice imports from Burma. But there is reliable evidence to show that not only in these areas but also in most parts of India the food situation had already deteriorated to such a degree that any considerable reduction in the food supply, from whatever cause, must have driven the people over the line that separates scarcity from famine. The Bengal Famine Commission report makes it clear that what may be called "pre-famine" conditions exist throughout the greater part of India.

You may suspect that this is an exaggerated statement; surely if the situation had been so serious it would have caused alarm and have given rise to a searching inquiry. It may seem incredible that so little attention was paid to the repeated warnings of danger, but there are several factors which help to explain the attitude of fatalistic indifference that prevailed. There is the traditional belief in "the Unchanging East," so that the very possibility of the revolutionary change that was taking place was contrary to all preconceived ideas. There was also the lack of reliable information which would have shown the extent of the change. Perhaps most important of all is the fatal tendency of human beings to refuse to meet trouble half-way. India is not the only country in which the Governments and leaders of public opinion have been apathetic in the presence of impending calamity. Let me quote a dramatic example of a similar state of affairs. In the course of a speech delivered in 1936 Mr. Churchill used these words: "I have been staggered by the failure of the House of Commons to react effectively against these dangers," and "I say that unless the House resolves to find out the truth for itself it will have committed an act of abdication of duty without parallel." Most of the other countries of the world showed a similar failure to react to danger in the pre-war days, so that there is no force in the argument that things cannot be so bad otherwise there would be signs of alarm. It must be concluded that human beings in general suffer from a defect, a kind of blind spot, in their psychological vision, which prevents them from seeing the signs of approaching disaster.

I do not propose to engage in the fruitless task of trying to fix the blame for past neglect. When things go wrong it is usual to look for a scapegoat or to blame the Government, but in the present case there would be great difficulty in finding judges and a jury who are themselves free from a share in the responsibility. The situation in India is like that of Britain on the eve of the last war, and the one thing needed is for all to sink their differences and unite in determined action to contend against the common danger.

What Can Be Done?

You will ask—What can be done? If the question were—What could be done? it would be easy to give a reply. It would be—Set about securing the immediate observance of the basic laws of health. I do not mean some of the laws, because already strenuous efforts are being made to comply with part of the health code dealing with the prevention of infection and the increased production of food. But there is only too much evidence that when everything possible has been done in these directions there will still be a great gap between the amount of food that will be available and the number of mouths to be fed. As soon as more food has been provided and infectious diseases have been satisfactorily controlled there will be a further up-surge in the rate of increase in the population, and the problem will be as far from solution as ever: the only difference will be that it will have become greater and more difficult to solve.

It is true that ambitious plans have been proposed for such an increase in the production of food that there might be no need for some years to come to tackle the thorny question of controlling the birth rate. The weakness of these plans is that their success is conditional on the possibility of persuading the people to make drastic changes in their outlook on life and manner of living. Such changes as will be involved in the abolition of uneconomic small-holdings and the elimination of millions of useless cattle will certainly be resisted quite as fiercely as the changes needed to control the number of births.

In any case it seems certain that a satisfactory balance between population and food supply cannot be reached without making very strenuous efforts not only to increase the food supply but also to restrict the growth of population.

Root Cause of the Trouble

The crux of the whole problem is how to bring about the necessary change in the outlook on life of the people; I still think that the best way of dealing with this essential aspect of the situation would be by the appointment of a Commission of the kind asked for more than 20 years ago by the medical research workers of India. These workers at four successive annual conferences, held in 1923-6, unanimously adopted resolutions, proposed by myself and seconded by the late Major-General Hutchinson, Public Health Commissioner with the Government of India, in which an appeal was made to Government for the appointment of a Commission, chiefly non-technical, for the purpose of making a thorough inquiry into the wastage of life and economic depression which were regarded as being due to causes that were capable of being removed. The reply of Government was that the proposed Royal Commission on Agriculture would be the most suitable body for making inquiries into the evils referred to in the resolution.

When the report of this Commission appeared it was found to contain one pertinent reference to the root cause of the trouble. It was pointed out that "an increase in the yield of crops would merely postpone the effects of the growing pressure of population on the soil," and that "no substantial improvement in agriculture could be effected unless the cultivator had the will to achieve a better standard of living." It was also stated that "the responsibility for initiating the steps needed to effect this improvement rested with Government."

These significant words completely justified the appeal by the research workers for an investigation into the non-technical aspects of the problem; it was clear that the social and psychological aspects of the question could not be properly investigated by agricultural experts, but only by persons familiar with the mentality and conditions of life of the villagers themselves. The policy of Government has always been directed towards effecting improvements that could be carried out by adminis-

ive action, and too little attention has been paid to the principle that what is done by the people themselves always counts greater and more lasting benefits than anything that is done for them by outside agencies. When each family learns how to plan its life on right lines the improvement effected in this way will be multiplied by many millions and the total results will be enormous.

Repeated appeals have been made for an investigation on these lines, but unfortunately they were not backed up by the weight of public opinion needed to convince Government that there was a real demand for such an inquiry. In the absence of this widely expressed desire for a Commission the Government may well have feared that if they had taken the initiative their action would have been regarded as an attempt to distract attention from embarrassing political issues. Whether for this or other reasons, no convenient time could ever be found for a study of the subject from the broader point of view.

Now that the shock caused by the Bengal famine has created a sense of danger the atmosphere is more favourable for a searching inquiry. The persons best fitted for carrying out the inquiry are enlightened Indians; but especially Indian women, because the women are the chief victims of the existing system, and because they have shown themselves far more ready than men to sink political and communal differences in their efforts to secure better conditions of life.

The objects of the inquiry would be to make an unbiased report on the social and other customs which play so important a part in causing ill-health and economic depression in the villages, and to recommend suitable action for bringing about the needed changes in these customs. The Commission would have to keep clear of all subjects connected with the special interests of political parties or communities. Disease is no respecter of races, creeds, or political parties.

Need for a New Outlook

The simplicity of the problem in principle and the obvious nature of the solution are in very sharp contrast with the extreme difficulty of applying the solution; but if the gravity of the situation were fully realized the people would be eager to unite in saving the country from disaster. One of the chief services that would be rendered by the Commission would be to create the sense of danger needed to convince the people of the need for a change in their plan of life.

What has to be done is clear—it is nothing less than to create a new outlook on life, which must be in accordance with the principles already stated. You will not expect me to anticipate the findings of the proposed Commission with regard to the method by which this outlook can be created. The working out of the method will indeed be a difficult task, though if the will to succeed is strong enough the modern resources of wireless broadcasting can enable the teachers of the life-saving knowledge to convey their instruction to every remote corner of India. Receiving sets can easily be installed in every village in India at a cost which would be negligible in comparison with the benefits resulting from education by word of mouth and the introduction of much-needed entertainment to the drab lives of the people.

I have not presented a plan; but only a plan to prepare a plan. The plan itself can be prepared only by educated Indians, on whom must rest the responsibility for saving their countrymen, and themselves, from a terrible disaster.

The reports for 1945 of medical officers of health should be prepared on the same lines as the report for 1944. Among subjects of current interest which should be included are tuberculosis (including the allowances scheme), venereal disease (including tracing of contacts and follow-up of defaulters), care of premature infants and of illegitimate children, and the steps taken to combat infestation. Arrangements should continue to be made for careful preservation of all records, including the statistics to be supplied by the Registrar-General. As regards water, the report should state: (i) whether the water supply has been satisfactory in quality and quantity; (ii) the number of bacteriological examinations and the results obtained, also the results of any chemical analyses; (iii) the facts about contamination of any kind and the action taken; (iv) the number of houses and the population supplied from public water mains (a) direct to the houses and (b) by stand-pipes.

CAUSES OF DELAYED MENSTRUATION AND ITS TREATMENT

AN INVESTIGATION IN THE WOMEN'S AUXILIARY AIR FORCE

BY

N. SHER, M.D., B.Sc.
Fl. Lieut., R.A.F.V.R.

The prevalence of amenorrhoea in members of the Women's Auxiliary Air Force on entry to the Service, without any obvious pathology in the uterus, adnexa, or any of the other body systems, prompted me to investigate this interesting syndrome.

The comparative absence of any important work on the subject of delayed menstruation in the English language up till about 1939 is to be wondered at. Schweitzer (1917) records that 4% of 2,016 gynaecological patients consulted between 1916 and 1917 suffered from *Kriegsamenorrhoe*, as the condition was then called: Comparable figures were offered by Graefe (1917), Grünebaum (1917), and Hannes (1917). Reviewing the situation in 1928, Teebken stated that 0.19% of the patients examined in 1914 suffered from *Kriegsamenorrhoe*, and this figure rose to 5.11% in 1917. The duration of the amenorrhoea was 2 to 24 months, and he believes that (1) a deficiency of first-class protein, (2) psychical disturbance, and (3) increased work are the most important aetiological factors.

With the above facts in mind, it was realized that a unique opportunity presented itself to pursue further the study of this condition in members of the Women's Auxiliary Air Force, in whom its occurrence was by no means infrequent. An attempt was therefore made to investigate (1) the incidence of delayed menstruation in airwomen, (2) the relationship of delayed menstruation to occupation, (3) the relationship, if any, to the protein content of the diet, and (4) a form of therapy. It was also hoped that endometrial biopsies would be performed, but this was not possible owing to factors beyond my control.

Incidence of Delayed Menstruation in Airwomen

The incidence of amenorrhoea in airwomen was investigated in nine Royal Air Force stations: the total number involved was 2,312. The girls were questioned during what is known as an F.F.I. examination (i.e., free from infection), which is done as a routine with frequent regularity in an airwoman's career to exclude the presence of the ordinary skin infections. They were specifically interrogated with regard to (a) regularity or otherwise of the menstrual cycle, (b) history of amenorrhoea on entry to the Service, (c) dysmenorrhoea, (d) menorrhagia. Table I gives a summary of the results obtained.

TABLE I.—Incidence of Menstrual Anomalies in 2,312 Airwomen

Year	Normal and Regular	Amenorrhoea on Entry to Service	Dysmenorrhoea	Menorrhagia	Completely Irregular	Total
1939	5	—	—	—	—	5
1940	186 (84.5%)	6 (2.7%)	11 (5%)	2 (0.9%)	15 (6.8%)	220
1941	689 (83%)	52 (6.2%)	31 (3.7%)	14 (1.6%)	44 (5.3%)	830
1942	753 (82.3%)	59 (6.4%)	33 (3.6%)	18 (1.9%)	52 (5.6%)	915
1943	285 (83.3%)	22 (6.4%)	13 (3.8%)	1 (0.2%)	21 (6.1%)	342

From the figures, therefore, it will be seen that delayed menstruation constituted one of the greatest menstrual abnormalities in the 1941-3 period, and invariably dated from the time of entry to the Service.

Relation between Delayed Menstruation and Occupation

The total number of cases of amenorrhoea in the present series was 139. Of these, 52 (37.41%) were clerks, 20 (14.4%) were cooks, 16 (11.5%) were drivers, while 9 (6.4%) were employed on general unskilled duties. Telephone operators numbered 9 (6.4%), 8 (5.7%) were equipment assistants, and 7 (5.03%) were batwomen. Flight mechanics numbered 4 (2.9%), and 3 (2.1%) were waitresses. Only 2 (1.44%) occurred in each of the following trades: administrative staff, safety equipment workers, wireless operators, tailoresses, and instrument repairers. Finally 1 (0.72%) was a sparking-plug tester. The greatest number of cases of amenorrhoea therefore occur in those with sedentary occupations.

Length of Menstrual Delay.—The length of the menstrual delay (to the nearest month) in 139 cases of amenorrhoea was calculated from the time of the first missed period (Table II).

TABLE II.—Menstrual Delay in 139 Cases of Amenorrhoea

Menstrual Delay in Months	No. of Cases	%
1	9	6.47
2	29	20.86
3	62	44.64
4	16	11.51
5	5	3.59
6	15	10.79
7	3	2.15

It will be noted that 62 (44.64%) had a delay of three months, while only 3 (2.15%) had a delay of seven months.

Relation between Delayed Menstruation and the Protein Content of the Diet

Teebken's contention that a deficiency of protein is one of the most important factors in the production of delayed menstruation could not be allowed to go unconfirmed. As a result, the diets of the Royal Air Force stations in question were investigated. One specimen menu drawn at random will be quoted in some detail to illustrate the method of calculation of the various quantities of protein, carbohydrate, and fat in the diet (see Table III). Many other menus were similarly investigated, but the results of only some of these will be recorded (see Table IV).

TABLE III.—Specimen Menu

Menu	Weight (oz.)	Calories per oz.	Carbohy- drate* (g.)	Protein (g.)	Fat (g.)	Total Calories
Breakfast						
Porridge (dry)	1	116	20.6	3.8	2.5	116
Bacon (fried, streaky)	1½	149	0.0	8.7	16.84	191.57
Bread (national)	8	64	102.4	22.4	4.0	512
Butter	½	226	Tr.	0.05	12.1	113
Milk, tea, etc.	4	19	5.6	3.6	4.4	76
			128.6	38.55	39.84	1,008.57
Dinner						
Beef stew	6	31	4.2	18.6	10.2	186
Potatoes (old, boiled)	8	23	44.8	3.2	Tr.	184

Total			459.2	129.01	142.84	3,582.5

* The carbohydrate is expressed as monosaccharides

NOTE.—To convert individual nutrients into terms of calories the figures 3.75, 4.1, and 9.3 are used for carbohydrate, protein, and fat respectively. (McCance and Widdowson, *The Chemical Composition of Foods*, 1942)

A glance at Tables III and IV will indicate that in no case does the weight of the protein ration fall below 100 g. daily, and in most cases it is much more. Allowing 1 g. protein per kg. of body weight as adequate, it will be seen that the quantity of protein in the diet is sufficient for an airwoman of average

TABLE IV.—Carbohydrate, Protein, and Fat Content, and Calorie Values of 5 Daily Menus

Diet	Carbohydrate (g.)	Protein (g.)	Fat (g.)	Total Calorie
1	388.5	166.0	168.3	3,705
2	373.0	162.4	159.0	3,545
3	410.0	151.0	160.0	3,645
4	430.0	136.0	145.5	3,523
5	377.5	159.0	162.0	3,575

weight. That a deficiency of protein is an essential factor in the production of delayed menstruation can therefore have little foundation on fact. No conclusion can be reached as to the vitamin and salt content of the diet. We can, however, assure that if the menu is well composed and contains the allotted quantities of milk, butter, eggs, and fruit, the vitamin and salt content will suffice for normal requirements.

A Form of Therapy

The adoption of a rational basis for therapeutics depends on the accurate differentiation of the various types of amenorrhoea. A thorough clinical examination to eliminate all organic and obviously endocrine causes is essential if any success in therapy is to be expected. Prostigmin methyl sulphate has been found to be effective in the treatment of delayed menstruation by Soskin, Wachtel, and Hechter (1940), Wilkenstein, Settel (1942), and Snider (1943) in America, and by Friedmann (1944) in this country. The usual dose is 1 to 2 ml. of a 1/2000 solution injected intramuscularly on three successive mornings.

The apparent success of the above authors induced me to treat a number of airwomen suffering from menstrual delay with a parasympathetic mimetic drug. For this purpose carbaminocholine chloride (carbachol B.P.) was chosen in the form of the proprietary preparation moryl (oral),* each tablet containing 0.002 g. of active carbaminocholine. Carbaminocholine chloride is a powerful parasympathetic mimetic. Its activity is greater than that of acetylcholine, its action is more prolonged, and its effects can be inhibited by atropine sulphate.

Nine cases suitable for treatment were chosen, and the Zondek-Ashheim test was performed in each instance to eliminate the possibility of early pregnancy. Realizing that the patients might menstruate as the result of the psychological effect of any drug, five of the cases were given the carbaminocholine while the other four had a placebo containing starch, lactose, and saccharin. Neither group knew whether they were receiving the placebo or the active drug.

The first five cases were treated with 1-1 tablet of moryl (0.001-0.002 g. carbachol) t.d.s., while the other four were treated with 1 tablet placebo t.d.s. When the latter did not menstruate after 3 to 4 days' treatment the placebo was replaced by the active drug. The ages of the patients were between 19 and 30 years and the menstrual delay was from 6 days to 19 months. In seven of the nine cases the menstrual period was precipitated in 17 to 96 hours after the onset of treatment; one patient menstruated in 35 days; while the other bled after treatment with placebo only. The dosage of moryl required was 3 to 15 tablets—0.006-0.030 g. carbaminocholine chloride.

The histories of the cases are summarized in Table V. The facts in the table require further comment. (1) In Case menstruation occurred in 35 days. It is not suggested that the drug was responsible for the bleeding. Further, the succeeding period was absent. I believe that this may have been a mild example of the adipo-genital syndrome as evidenced by excessive weight and hypoplasia of the genitals. (2) In Case menstruation occurred after administration of three tablets of placebo only. There are two possible explanations: (a) the onset of the menstrual period was merely coincidental with the treatment; (b) the patient was a rather depressed individual and the interview was partly in the nature of a psychiatric examination, which may have facilitated her adjustment to her environment and so helped to precipitate the period.

It is apparent that a larger series of cases would have to be treated before any definite conclusions could be reached. How

* This drug was kindly supplied by Savory and Moore, 14 Lawrence Road, London, N.15, who also supplied the placebos in generous quantities.

TABLE I—Effects of Carbaminocholine Chloride and Placebos in 9 Patients

Age	Menstrual Defect	Treatment	Total Dose Carbaminocholine	Results	Time from Onset of Treatment to Preceding Period	Abnormal Symptoms	Success in Period
21	5 months	1 tab morlyt d.s.	0.012 g	Menstruated. Bled 5 days	96 hrs	Eyes aching	Normal
20	6 days	"	0.006 g	" " 4 "	17 hrs	"	"
25	4 months	"	0.012 g	" " 6 "	24 hrs	"	"
19	26 days	"	0.016 g	" " 3 "	60 hrs	Headaches	"
24	31 months	"	0.008 g	" " 4 "	18 hrs	"	"
21	19 "	1 tab placebo t.d.s.	12 tabs placebo	Nil	"	Nil	"
		1 tab morlyt d.s.	0.03 g	Menstruated. Bled 10 days	35 hrs	"	Abnormal
	31 days	1 tab placebo t.d.s.	3 tabs placebo	" " 5 "	24 hrs	"	Normal
19	7 months	1 tab placebo t.d.s.	12 tabs placebo	Nil	"	"	"
		1 tab morlyt d.s.	0.016 g	Menstruated. Bled 5 days	60 hrs	"	Normal
		1 tab placebo t.d.s.	12 tabs placebo	Nil	"	"	"
23	2 1/2 "	1 tab morlyt d.s.	0.018 g	Menstruated. Bled 4 days	72 hrs	Flooding	"

it would appear that carbaminocholine chloride was successful in precipitating bleeding in seven of the nine cases tested and it is therefore felt that the drug merits more extensive clinical trials in all cases of amenorrhoea in the absence of organic disease

Conclusions

To provide a satisfactory explanation for the cessation of the bleeding phase of the menstrual cycle in a healthy young woman, resulting from a sudden change in environment, is admittedly difficult. However, enough experimental data exist to allow me to postulate (with some trepidation) an interesting hypothesis which, if not yet valid, is at least in accord with fact. The following experimental evidence is at our disposal

- (1) The hypothalamus probably governs our emotional response to external environment, that response being expressed through the hypothalamic-sympathetic and parasympathetic nervous system connections (Masserman, 1941; Tucker, 1941)
- (2) Hypothalamic stimulation produces autonomic discharge, the nial effect being dependent on the preponderance of the sympathetic or parasympathetic nerve fibres (Gellhorn, 1941)
- (3) The injection of oestrone in ovariectomized animals causes a hyperaemia of the uterus and an increase in its acetylcholine content. Bleeding may depend on the presence of the latter (Reynolds, 1939)
- (4) Lutenizing hormone is released from the anterior hypophysis by an acetylcholine-like substance, liberated by the hypothalamus (Aubenhau and Soskin, 1941)

Armed with these facts, we can now see that environmental stress or psychic trauma, no matter what its origin, will activate the hypothalamus to produce adrenaline and acetylcholine. While the sympathetic fibres predominate, however, then a relative deficiency of acetylcholine will be present and thus bleeding will be suppressed, owing to either (a) a local deficiency of acetylcholine in the uterus, or (b) absence of luteal hormone and consequently of corpora lutea

One other phenomenon requiring further elucidation is the reason for the development of amenorrhoea in some and not in others when exposed to the same environment. It is a truism say that individuals differ in their reactions to the same environment. This ultimately is an expression of character, and probably depends on the degree of representation of the sympathetic and parasympathetic nervous systems in the cortex. If the two systems are represented more or less equally in the cortex, then the adrenaline/acetylcholine balance in the blood will not be disturbed on exposure to environmental change, and the menstrual cycle will remain unaffected

His conception may also be invoked to explain the cessation of the bleeding phase of the menstrual cycle in a host of other cases—e.g., in probationer nurses, on going away for a holiday, and in those who fear the onset of pregnancy, etc. The common precipitating factor in all is a complete change of environment, creation, and work, or a period of mental and emotional stress leading to overactivity of the sympathetic nervous system

The belief that the pituitary gland is "the leader of the endocrine orchestra" is perhaps not now entirely true, and it may, in fact, play "second fiddle" to the hypothalamus

Summary

The incidence of delayed menstruation in 2,312 airwomen was calculated

It was found that sedentary workers were mainly affected

The theory that protein deficiency is responsible for the amenorrhoea is disproved

Seven of the eight cases of delayed menstruation treated with carbachol B.P. menstruated while one bled with a placebo only

The possible mechanism of production of delayed menstruation is discussed

I am indebted to Air Marshal Sir H. E. Whittingham, Director-General of Medical Services, Royal Air Force, for permission to publish

PENICILLIN SPRAYS AND UPPER RESPIRATORY TRACT INFECTION

87

F. A. KNOTT, M.D., F.R.C.P., D.P.H.

Director Bacteriological Department, Guy's Hospital

AND

J. B. BLAILEY, F.R.C.S., F.R.C.O.G.

Assistant Obstetric Surgeon, Guy's Hospital

A natural result of the increasing availability of penicillin will be its use by the public in nose and throat sprays, often on medical advice, but sometimes without it. Already there seems to be a growing belief, based mainly on random clinical results that such sprays are useful in cases of respiratory tract infection. Some direct evidence on this point may be appropriate

At the beginning of 1942 we started nose, throat, and skin cultures regularly taken from all patients and staff in the maternity department, with a view to minimizing the entry of streptococcal and staphylococcal infections and excluding carriers. Having first observed the course of bacteriological events for about a year, we put into operation a preventive routine, continuous cultural control being kept up as before. The resulting reduction in the incidence of ward sepsis we recorded in 1944. This improvement has been maintained ever since, but always at the expense of a certain number of tiresome exclusions, particularly among nurses in training and among students. Early in 1944 in the hope of getting infected individuals back to duty more quickly, frequent regular nose and throat spraying with penicillin was started. The routine adopted was to spray both sides of the nose and throat by means of an all-glass "crystal" atomizer (Rogers) for about one minute at three- to four-hourly intervals. The solution used contained penicillin (usually calcium), 1,000 units per ml. Test cultures for freedom from infection were made in the morning before the spray had been used. If a negative result was obtained spraying was stopped for two or three days and swabbing repeated to make sure. Therefore as regards the persistence of infection following

examinations in food inspection and inspection of premises, students are to keep a day-book of their practical work throughout the course and examiners are to take account of it in assessing marks.

In some ways the new courses will be more exacting than the old for students, and also for teachers, because instruction will be more demonstrational and not merely supervisory, as so much laboratory instruction tends to be. There are, however, exemptions from classes for students with appropriate clinical or public health experience, and the combination of academic study with approved part-time practical occupation, which the scheme makes possible, should provide a good training for medical officers of health. It should be clearly understood that the new system is intended to provide an adequate basic training in public health, by means of the preliminary course and certificate, for all officers wishing to work in a public health department. The limited numbers who aim at being medical officers of health will go on to the diploma; the others, presumably, will seek a higher qualification in the particular specialty in which they are engaged, whether it be child health, tuberculosis, infectious diseases, venereal diseases, or some other recognized field of public health work. It is to be hoped that employing bodies will fall into line and cease to require all entrants to the service to hold a diploma or degree in public health.

FLUORESCENT TRACERS

In this age of atomic energy much work has already been done on the use of radio-active isotopes for tracing the metabolism of compounds in the animal body. And now, following the identification of tubercle bacilli by fluorescence microscopy, it is interesting to read that the property of fluorescence is being used to trace the location of particles in tissue.

Yagoda and Donahue¹ have shown that many minerals the dust of which is toxic are also represented by natural specimens having the property of fluorescence under ultra-violet rays. The fluorescent mineral is identical with the more abundant non-fluorescent ones in gross chemical composition, hardness, density, and solubility; it differs only in containing a trace constituent held in solid solution which serves as an activator for the transformation of ultra-violet rays to visible light. The fluorescence of these substances, inhaled as a finely divided dust, persisted after being acted on by tissue fluids and reagent solutions used in the preparation and staining of thin sections. The sections of the lung on a slide could also be incinerated at 400° C. in a muffle furnace without destroying the fluorescence of the mineral dust; the fine dust particles were in fact best observed in the resulting ash pattern. Yagoda and Donahue describe experiments with three fluorescent materials: willemite, a zinc silicate with an intense green fluorescence; hyalite, a hydrated variety of amorphous-free silica with a pale-green fluorescence; and scheelite, a calcium tungstate with a fluorescence which varies from blue to yellow according to the molybdenum content. The lungs of a rabbit were insufflated with powdered willemite which passed a 100-mesh screen, and, after 18 hours, examination of the lungs and trachea under ultra-violet light showed the dust adhering as a continuous film on the mucous lining of the trachea and as scattered collections on the cut lung surface, and microscopical investi-

gation disclosed that the particles were located within the bronchi and alveoli. In the second experiment hyalite was injected subcutaneously into a rabbit, which was killed 30 days later. Sections of the nodules at the points of injection, when examined under ultra-violet rays, revealed the presence and distribution of the foreign dust particles by their characteristic pale-green fluorescence. Lastly, animals were exposed for several months to scheelite, and here fluorescence microscopy showed the particles to be located in dense deposits within the interalveolar septa, usually in the vicinity of small- to medium-sized bronchi. Finely granular, evenly distributed particles were also seen in the septa, and in lesser amounts uniformly distributed throughout the lung. Some was found in the periphery of the peribronchial lymph nodes.

This work suggests that fluorescent-tracer technique may become a valuable method of histochemical investigation of inhaled dust, particularly in laboratory investigations designed to simulate conditions in mining or industry. The fluorescent mineral may be used as the dust for investigation, or it might be added in small quantities to the non-luminous variety; or where a fluorescing specimen of identical chemical composition is not available the tracer technique might be used by adding a fluorescent inorganic preparation having density, solubility, and particle size distribution similar to those of the dust under investigation; it might be assumed that wherever a fluorescent particle was observed it was accompanied by the dust.

STUDENT HEALTH SERVICES

The Social and Preventive Medicine Committee set up by the Royal College of Physicians of London in 1942 has now presented a third interim report, giving further and closer attention to its earlier recommendation "that student health services should be available in every medical school, and that under the general supervision of the head of the department of social and preventive medicine they should be used as an instrument of teaching." No final decisions could be reached as to the medical staffing of such services, especially in regard to the provision of treatment, until more was known about a National Health Service. It was also premature, for the same reason, to set out any details of a "student health centre" of the type suggested in the committee's original report. Nevertheless the evidence, mainly from students themselves, revealed such a disquieting position that it seemed urgently necessary to bring the matter to the notice of university authorities. Moreover, though the committee originally confined itself to the narrower question of the health of medical students, it became clear that all university students must be considered. The present report therefore takes up the broad issue of health services for the undergraduate (and the resident graduate too) and gives guidance on general lines of policy without going into detailed suggestions. The evidence before the committee has convinced it that there is a serious amount of sickness among university students; that many university authorities are almost wholly indifferent to any measure of preventive medicine; that facilities for care of sick students (except those suffering from serious illness) are sadly deficient; and that matters of diet and lodgings are in some instances given only perfunctory attention from the point of view of health. The recommendations, briefly summarized, are as follows: (1) Universities should accept greater responsibility for the health of students. (2) Arrangements should be made for medical examination after entry and periodical examinations during the student's stay, to detect physical and mental disabilities and to indicate available means for

ephedrine was then given and the recording repeated after one hour (former tentative experiments had shown that the maximum effect of ephedrine is usually not reached before 50 minutes and lasts till 2 or 3 hours later). If there was no change in the vital capacity and the wheeze, and if there were no signs of intolerance—tremor, sweating, nausea—another dose was added, and the recording repeated after another hour. If necessary, the whole procedure was repeated once again. As the additional doses of ephedrine follow in hourly intervals their action is superimposed, and the effect is similar to what would have been achieved by a single large dose equal to the two or three consecutive ones. In other cases the ephedrine effect was investigated by giving a tentative dose thrice daily and recording the effect on the vital capacity before and after 2 to 3 days.

Altogether 65 patients suffering from bronchial asthma or emphysema came under observation. In 14 of them the asthma was slight; these reacted to a few small doses of ephedrine and became free from attacks and wheezing for a long interval. They were usually young—most of them adolescents, some between 20 and 30—and their vital capacity was not reduced when they were not in an attack. These cases do not present any problem so far as ephedrine dosage is concerned, and we shall therefore not deal with them here.

Of the remaining 51 patients, 14 were typical severe asthmatics of the younger (extrinsic) type. The other 37 were cases of emphysema. Most of them were over 30 and many over 40. Some had had typical bronchial asthma for many years, but the majority showed a long history of cough or repeated bronchitis, originating 5 to 10 years ago, which was followed later by breathlessness on exertion. In many of these, asthmatic attacks had developed at a late stage of their history, and were apparently not the cause of the emphysema. These 51 patients had one characteristic in common—a nearly continuous wheeze. In most of them, also, a reduction of the vital capacity, radiological signs of emphysema, and an increased reserve air were present. All therefore may be classed as emphysema, although in some of them bronchial asthma could be traced as the principal cause.

In order to compare the ephedrine effect in these 65 chest patients with its effect in other subjects we have also investigated its action in 4 normal persons and 8 patients with heart disease. There is not much change in the vital capacity after the usual dose of 1/2–1 gr. (32–65 mg.). The differences are mostly less than 100 ml., and they lie in both directions. This negative result was to be expected, as Voegtili and Verzář (1945) have shown recently that the vital capacity in normal persons is not influenced by adrenaline. It should be emphasized that all four subjects experienced slight side-effects of ephedrine—tremor and palpitations. This shows that the dosage was near the limit of what was tolerable. The same result has been obtained in 8 patients with heart disease. These patients had been in congestive failure for various reasons some time before, but showed now no external signs of failure. In none was congestion of the jugular veins present, but most of them showed a reduced vital capacity and the chest skiagrams revealed increased vascular markings. They had no bronchitis. Although ephedrine did not influence their vital capacity significantly, the side-symptoms were more pronounced in this group than in the normal subjects.

Patients with Bronchial Asthma and Emphysema

The difference in the reaction of these patients is striking. Although there are a few who feel palpitations or tremors after the usual small doses, the great majority do not, and it is surprising to see how large doses of up to 4 gr. (0.25 g.) are tolerated without any toxic effects. Even prolonged dosage of 3–3½ gr. (0.2–0.225 g.) t.d.s. has produced no ill effects in such patients (as has been found by Middleton and Chen, 1927). The effect on the bronchial spasm, as shown from the increase in vital capacity, is pronounced.

We can divide our 51 patients, according to their response to ephedrine, into four groups: (1) those who respond to doses up to 1 gr.; (2) those who respond to higher doses; (3) those who are hypersensitive to very small doses; and (4) those who are refractory or nearly so to any dosage.

(1) *Those Responding to Doses up to 1 gr.*—The vital capacity increases by 200–400 c.cm. Only 5 cases in our series of 51 reacted

in this way, which is the usual reaction seen in light asthmatics—the group we have excluded from this investigation.

(2) *Those Responding to Higher Doses.*—The accompanying table gives the results in 28 patients. In some of them the negative or

Table showing Results with Doses above 1 gr.

Experiments with suboptimal doses are given in italics.

* Effect of one single dose. † Continuous effect of 1 g. doses, usually on the third day of dosage. ‡ Inhalation treatment was given at regular intervals during the whole course. § After six days of 1½ gr. t.d.s. the vital capacity was back to 1,800 and 1,750 ml. Under 2½ gr. t.d.s. it increased again to 2,010.

very slight effect of smaller doses is given in italics beside the larger and effective doses. In the first part of the table the immediate effect of a single dose of ephedrine is recorded; in the second part the effect of continuous dosage over several days. In the 7 remaining cases of this group the clinical improvement was definite, but the effect was not recorded by the spirometer. In some of these cases, after the beneficial effect of ephedrine had been ascertained, it was continued with other treatment, especially inhalation of various substances. Breathing exercises were given in many cases throughout the whole course of treatment. In all these cases ephedrine increased the vital capacity considerably (the average was 518 ml.), and the subjective relief was great. Even an increase of 200 ml. was usually accompanied by easier breathing, and in the case of advanced emphysema the breathlessness on slight exertion improved considerably. The wheeze disappeared in some instances, in others it diminished in intensity, while in yet others it remained unchanged in spite of the subjective relief. It is quite clear from the recorded reaction of these patients to smaller doses that they were quite insensitive to them, whereas they reacted favourably to higher dosage, these latter patients being in a higher proportion than those reacting to smaller doses. It would be interesting to find whether there are special clinical characteristics for this group. While it is impossible to differentiate accurately among such a small number of patients, it can be said that the largest doses were required by patients who were in a severe asthmatic state of long duration or had severe emphysema. Patients with asthma-free intervals usually did not require high dosage, but responded to doses near 2 gr. (0.13 g.).

Acquired Ephedrine Tolerance

In the cases described above the resistance to small doses seems to be genuine, as many of them had never been treated with ephedrine and none of them recently. We have, how-

ever, watched other patients who acquired a tolerance to ephedrine.

When, for instance, a dose of 1 gr. was given thrice daily with good success it was found that after a short time—often after 3 or 4 days—the vital capacity decreased again to its original value. If the dose was then increased to $1\frac{1}{2}$ gr. (0.1 g.) the vital capacity increased again, only to lose its effect after the same interval. (An example for this—Case 28—is given at the end of the table.) In this way the amount of ephedrine had to be increased at short intervals till a dosage was reached (usually between 3 and 4 gr.) at which toxic symptoms, mostly nausea, appeared and prevented further increase. This phenomenon is clearly seen only with three daily doses where effects overlap slightly in the daytime. With two daily doses resistance is not acquired so easily, but except in the case of slight and transient attacks this dosage cannot be relied on to give relief. In such slight cases the attack is often cut off by two or three doses and the drug can be omitted again for good. In those cases, however, in which a continuous wheeze, even of a moderate degree, has developed, a long-lasting ephedrine effect is desirable, and in such cases the acquired tolerance is a great obstacle. Fortunately, the resistance is lost as quickly as it is acquired. When the primary efficient dose becomes inefficient, ephedrine can be omitted without any ill effect, and after a short while (often 3 to 4 days) the previous degree of sensitivity has been restored, and the previous dosage can be given with the same good result.

The tolerance for ephedrine develops very quickly. This could be seen when side-symptoms developed on the first day of treatment. When the first dose given to a patient was near his limit of tolerance he often complained of palpitations or tremor. If these were only very slight the dose was not reduced, and in nearly all cases the symptoms disappeared on the second day. This "first-day side-symptoms" phenomenon became very common in our experience. Similar observations have been made by Althausen and Schumacher (1927) and Hollingsworth (1927).

In the circumstances it does not seem useful to give an efficient dose of ephedrine for longer than about 4 days. Then the dose must be increased or omitted altogether. We found that the latter method is satisfactory in all cases except those which still require an uninterrupted ephedrine effect. Most cases do not, and if the ephedrine is omitted for 3 or 4 days the vital capacity decreases only a little and the condition remains subjectively unchanged. After this the previous dosage can be resumed and new improvement obtained or, at least, the former maximum vital capacity restored. The procedure can be continued for a time. Later, when the asthmatic state has been overcome, it can be discontinued, and if a new attack should afterwards occur the same routine can be employed again.

(3) *Patients Hypersensitive to Ephedrine.*—In our series 3 patients were observed who were hypersensitive to doses of less than $\frac{1}{2}$ gr. (32 mg.). If necessary these patients can be made tolerant by starting with doses of $\frac{1}{8}$ gr. (8 mg.).

(4) *Patients Refractory to Any Dosage.*—Another group of refractory cases comprises those which are not hypersensitive but hypersensitive. Doses of 1, 2, or even 3 gr. have either no influence or only a very small influence, and if the dose is further increased heavy toxic symptoms appear. In addition, small improvements, if achieved, are lost quickly through an additional acquired tolerance. Such cases are not very rare. We have seen 8 in our series of 65 cases.

Discussion

These results present the ephedrine effect as much more complicated than it has appeared till now. The individual variation of the response is greater than to most other drugs, and even in the same subject the response varies with the tolerance which may have been acquired, and possibly with the changing severity of the bronchial spasm. Whereas in slight asthmatic conditions the customary small doses are sufficient in a higher percentage of cases (according to the survey of Chen and Schmidt, 1930, about 2 out of every 3 patients seem to have improved), in our series of 51 severe cases only 5 responded to this dosage. Thirty-five patients responded well to high doses, which seem to have been employed in the past only rarely (Middleton and Chen, 1927; Christopherson and Broadbent, 1934). The remainder were either hypersensitive to the drug (3) or refractory (8).

These facts make its use difficult, and they explain why in so many cases no satisfactory results are achieved with a chance dosage. The practitioner will find it difficult to test the sensitivity to ephedrine by means of the spirometer, but in hospital the method could easily be used, and it is suggested that every patient who does not respond to the ordinary oral ephedrine doses should have his vital capacity estimated in order to find out the correct dosage. The advantage of such a procedure is great, as the proportion of improvements under ephedrine increases considerably. Therapeutic measures at our disposal in such severe cases are neither numerous nor very effective, and every possibility should be utilized. These patients, with their breathing capacity often reduced to a minimum that allows hardly any movement, will be relieved greatly by an increase in vital capacity of even 200 or 300 ml.

Compared with this possibility of a success, the side-symptoms which may appear should not act as a deterrent. The symptoms of slight overdosage are palpitations, tremor, nausea (altogether in our series we have only twice seen bladder symptoms—frequency—and once mydriasis which disturbed vision). They have never developed to a degree which was in the least dangerous to the patient, and they often disappeared spontaneously on the second day. If they did not, a slight reduction in the dosage at once led to their disappearance. The blood pressure, which was taken at frequent intervals and often daily, did not show any pathological variations under ephedrine. In these circumstances a slight overdosage can hardly be regarded as dangerous, and should be considered justifiable in view of the possibility of a success. If a practitioner who has no spirometer at his disposal finds no response whatever to doses of 1 gr. t.d.s., it is suggested that he should make use of the higher dosages as described in this paper.

Although we regard oral ephedrine in the correct dosage as very efficient in the treatment of severe cases of asthma and emphysema, it is by no means the only one, and often other drugs, or inhalation treatment and physiotherapy, have to be used instead or in combination with it. It is outside the scope of this paper to comment on these other forms of treatment in detail. It should be mentioned, however, that there is one condition in which oral ephedrine seems of little use—namely, the acute asthmatic attack. In the acute attack quick relief is necessary, and oral ephedrine requires too long to become effective. In addition, particularly high doses seem to be required which are often not tolerated. This fact makes the treatment of the severe asthmatic or emphysematous person very complicated and difficult. If one has succeeded in improving such a patient's chronic asthmatic state considerably an acute attack may intervene which requires other forms of treatment, and one will have to wait till this attack has subsided to continue with the previous regime.

Summary

While some subjects are highly sensitive to the customary doses of ephedrine ($\frac{1}{4}$ gr.—1 gr.), many patients with bronchial asthma and emphysema are insensitive to them, especially the more severe cases that are in a chronic asthmatic state.

These patients often react well to high doses (2 gr.—3 gr.) and without any toxic symptoms or signs. This is shown by the immediate increase of the vital capacity, the frequent disappearance or diminution of the rhonchi, and the subjective relief.

Ephedrine tolerance is acquired quickly. If it is given 3 or more times daily it loses its effect soon—often after 3 to 4 days. If the dose is increased then, the higher dose will have the same effect as the former small one. If a patient has become tolerant to a certain dosage, and the drug is omitted, he will regain his former response to this dosage usually after 3 to 4 days.

An intermittent treatment with the primary effective dose is therefore suggested. It may play an essential part in the rehabilitation of these patients, who usually are regarded as invalids.

Most patients were admitted under Dr. A. Morland, to whom I am indebted.

TRANSIENT NON-SPECIFIC WASSERMANN AND KAHN REACTIONS IN A CASE OF INFECTIVE HEPATITIS

BY

J. H. WAELSCH, M.D., Sc.D. Prague

(From the LCC Group Laboratory, Archway Hospital)

This case and its laboratory findings are reported to show that, so far as careful investigation can indicate, falsely positive Wassermann and Kahn reactions may occur during the course of infective hepatitis and disappear during recovery. The case was one of a large series met with while working on a routine scheme for investigating jaundice and liver enlargement without jaundice which included serological tests. The other cases in the series and their laboratory investigations will be dealt with in a further communication.

Case Record

The patient, an unmarried female aged 21, suffered from nausea, heartburn, and vomiting for six days before admission, when she began to be jaundiced. Her urine was dark and she was constipated. She had not felt well for the previous four weeks and did not go to work for three weeks before admission. Four months

reaction (fixing 3 M.H.D. of complement when diluted 1 in 2) and a suspicious Kahn reaction after a fortnight, and negative reactions by both tests after 27 and 70 days; also, the examination of the cerebrospinal fluid yielded negative results. From these as well as from the lack of historical or clinical grounds one must conclude that the reactions were transient, biological, falsely positive ones. These findings stress also the necessity for carrying out quantitative serological tests, and repeating them should they be found positive, especially when there is a negative case report—in spite also of the fact that in this case two reactions were positive, which is generally accepted to mean the presence of syphilis.

Biological falsely positive reactions may occur with all tests in the absence of syphilis (because of the presence in the serum of a reagin (Kolmer) similar to that present in syphilis), in yaws 100%, leprosy 40 to 80%; malaria 12 to 20% or higher, depending on the stage, infectious mononucleosis 20%. Positive reactions may also be obtained in relapsing fever, rat bite fever 50%, possibly in Weil's disease and typhus. Furthermore, biological falsely positive reactions may occur in various acute infections including pneumonia though their incidence is probably less than 1 in 4,000 (Kolmer and Tuft, 1941). It is a widely held opinion that one can get non-specific reactions in cases of jaundice but the literature does not support this.

previously she was working in a factory where telephone cables were coated by a spray process but she emphasized that she herself had not come into contact with the chemicals used. Her past history revealed only a Bell's palsy two years ago. There were no history of venereal disease, no family history or recurrence of jaundice, and no probability of Weil's disease. The patient had not been abroad. Apart from the above named symptoms on admission, no abnormalities were found at the examination. Menstruation was normal, and gynaecological examination revealed no abnormalities or any signs of venereal disease. For a few days she was rather ill and dehydrated, and was still vomiting, the urine being dark and the motions clay coloured. Then she made an uneventful recovery, the jaundice fading in three weeks. The temperature, apart from a slight pyrexia of 99.8° on admission, was normal throughout her stay. In addition to the usual routine treatment for infective jaundice the patient was given haematinics and ascorbic acid. She was discharged on the 36th day after admission and was seen again, symptom free, on the 70th day.

Discussion

The Table shows that there was a strongly positive Wassermann reaction (fixing 3 M.H.D. of complement in dilutions of serum up to 1 in 40) and a positive Kahn reaction one day after the beginning of jaundice, a weakly positive Wassermann

A survey of tests conducted by Cummings *et al.* gives the following figures: neoplasms, 0 to 17%, fever (natural or induced), 0 to 2.3%, jaundice, none, pregnancy 0 to 19%, menstruation, none, acute tuberculosis, 2%. Another survey (venereal disease information, as quoted from Gradwohl, 1943) does not mention jaundice at all. Harrison (1931) and Kampmeier (1944) also refer to the widespread opinion of the occurrence of falsely positive reactions in many conditions, among them jaundice, based on the older literature, but they could not confirm these findings and relate them to errors in technique (see also Kolmer and Tuft, 1941). In this connexion the occurrence of falsely positive reactions due to smallpox vaccination seems worth mentioning (Lynch *et al.*, 1941).

Of 86 cases of the series, in which in addition to liver function tests serological tests were also performed, the reported case is the only one which gave transient positive reactions. The series included acute hepatitis, 35 cases (infective jaundice, 19, post arphenamine jaundice, 11—one died of acute necrosis of the liver: post-plasma-transfusion jaundice, 3, post malarial jaundice, 1, Weil's disease, 1), subacute hepatitis 3, obstructive jaundice, 20 (carcinomata with and without secondaries in the

liver, 17; gall-stones, 3; cirrhosis of the liver, 3; congestive heart failure, 7; amyloid disease, 3; amoebic disease, 2; carcinoma of the prostate, with secondaries of bone 1, and liver and bone 1; and miscellaneous 11.

The serum protein estimations show a disturbance of the albumin/globulin ratio one day after the jaundice began, which is also apparent from the very strongly positive Takata-Ara reaction. The high globulin value is also confirmed by the positive formol-gel test. There occurred also a flocculent turbidity after addition of water to the serum at the beginning of the protein estimation, which reminds one of the Klausner test. The later-performed investigations show a return to normality. This type of result is not uncommon in cases of hepatitis and other conditions, but one does not find positive Wassermann and Kahn reactions; thus one cannot merely on this basis explain the occurrence of the transient positive serological reactions. Do the findings in this case point to a special combination or pattern of lipid-globulin which produced the biological falsely positive Wassermann and Kahn reactions?

Summary

A case of infective hepatitis with transient biological falsely positive Wassermann and Kahn reactions is reported. Reference is made to the widespread belief that this occurs fairly often in hepatitis, but the literature does not support this opinion. Other laboratory findings discussed are those which may have some connexion with a non-specific serological reaction.

SUCCESSFUL SURGICAL TREATMENT OF ENTERIC GROUP CARRIER

BY

KENNETH FRASER, M.D., F.R.S.Ed., D.P.H.
County Medical Officer, Cumberland

AND

J. STEVEN FAULDS, M.D., F.R.F.P.S.
Pathologist, the Cumberland Infirmary, Carlisle

Over a period of years, up to January, 1944, sporadic cases of paratyphoid fever occurred in the Caldbeck district of Cumberland. The majority of these were among women in late pregnancy or recently confined. Between May, 1940, and December, 1943, four such cases of paratyphoid fever occurred in this area. There were one or two others among patients not belonging to this group. Certain of the cases terminated fatally.

The presence of a carrier in the district was suspected, but it was not until December, 1943, when the fourth of the cases among pregnant women occurred, that a pointer appeared indicating the possible location of a carrier. This fourth case, which terminated fatally, occurred in an adjoining village, which, while being in the area of the Caldbeck Nursing Association and within the practice of the Caldbeck doctor, was nevertheless quite distinct from Caldbeck village, and generally could be regarded as an extraneous area with little or no direct connexion with the area in which previous cases had occurred. The new common factor arising out of this fourth case was the attendance of the same doctor and the same district nurse-midwife.

Carrier's Case Record

A conference was held between the public health medical officers concerned and the practitioner. As a result investigations were carried out at the Cumberland Infirmary pathological laboratory in respect of the doctor and the district nurse, and cultures of *Bact. paratyphosum* B from the faeces and urine were obtained in the case of the nurse. The Vi and O agglutinins were negative, which is of interest in view of the belief that a chronic carrier usually has both to a high titre, and this test is frequently being used as a sieve to separate out chronic carriers, on the assumption that it is useless to examine Vi-negative cases. Investigations carried out during the

succeeding months proved the nurse to be a true chronic carrier. She has maintained throughout that she was not the source of the other cases, but was herself a victim of the disease acquired in the area. The question, however, is academic. She was suspended from the practice of midwifery, and ceased work as district nurse in the area. She entered the Carlisle Infectious Diseases Hospital for further investigation and treatment in January, 1944, and remained there as a patient until October, 1944. During the eighteen months which have elapsed since this nurse left Caldbeck no further cases of paratyphoid fever have occurred.

Dr. Felix, of the Ministry of Health laboratory, typed the *Bact. paratyphosum* B cultures by bacteriophage methods, and classified them as 3a. The cultures from the fatal case and two others which had subsequently occurred in the Caldbeck area—one being the parent of the fatal case—were, as would be expected, also 3a, proving that these were all infected by the same organism. By a fortunate chance the Cumberland Infirmary laboratory still had three other cultures of *Bact. paratyphosum* B, which had been obtained from cases that had occurred in Caldbeck, and had been dealt with in that laboratory, since 1940. These were also found to be type 3a. Of these three, one had been isolated from a puerperal case in March, 1943, which had been attended by the same nurse. The other two cases arose in 1940, both of them being in children. The cultures from cases of paratyphoid B investigated prior to 1940 were dead and could not be resuscitated. This was unfortunate, as it would have been interesting to find out if type 3a had existed in the area before the nurse took up duty in 1938.

From January, 1944, until October, 1944, the stools were examined at weekly intervals, and these always gave a profuse growth on desoxycholate media. During this period the nurse had two full courses of sulphaguanidine, which, as anticipated, had no effect on the condition. After admission to the Infectious Diseases Hospital she was x-rayed in February, 1944; her gall-bladder did not fill, indicating that some pathological condition was present. She was strongly urged to have a cholecystectomy done, but was unwilling to agree to operative treatment except as a last resort. In June, 1944, the first attempt was made to obtain a sample of her bile. A duodenal tube was passed, but owing to pylorospasm it would not enter the duodenum. While the tube was in the stomach she was x-rayed, and in spite of atropine and gastric massage it did not pass into the duodenum. Culture of the gastric juice was sterile. After giving magnesium sulphate a small quantity of bile-stained fluid was obtained. This, however, was strongly acid, and was sterile.

Dr. Felix, at this point, suggested a vaccine rich in Vi and O antigens. This was given intravenously in graduated doses in July, 1944. The patient had a considerable reaction, with a striking rise in the titre of her H and O agglutinins in the blood to 1 in 1,000 and 1 in 5,000 respectively. The Vi titre was 1 in 20. Her stools, however, remained positive. In August a duodenal tube was successfully passed. The gastric contents were negative, but the duodenal juices, after the administration of magnesium sulphate, yielded a growth of *Bact. paratyphosum* B. In September a second course of injections of intravenous vaccines was given, after which the stools were still positive, and the titre of the agglutinins in the blood remained the same. The mental condition of the patient had by this time altered. She was depressed and wept frequently, and had the impression that nothing effective in the way of treatment was being carried out. She still refused to have her gall-bladder removed, and in October, 1944, was discharged from hospital. Her stools were examined at monthly intervals from October, 1944, until March, 1945, and were consistently positive.

Early in 1945 the desirability of surgical treatment was again pressed on the nurse, and eventually she agreed to have her gall-bladder removed. In April, 1945, she was readmitted to the hospital, and Mr. J. N. Jackson Hartley, senior surgeon at the Cumberland Infirmary, removed the gall-bladder and also the appendix.

Surgical Procedure.—This consisted of cholecystectomy, appendicectomy, and freeing of ileum from the old scar. High spinal (percaïne) anaesthesia, with inhalation of cyclopropane, was given. A right paramesial incision from the ensiform process to below the umbilicus was made. The gall-bladder was about one and a half times normal size, and within the gall-bladder there was one stone about the size of the last joint of the index finger. No concretions could be felt in the hepatic and common bile ducts, and the pancreas was not indurated. The cystic duct was isolated and ligated. The gall-bladder was then dissected from the liver and, after tying the cystic vessels, the gall-bladder was removed. Though the appendix did not appear to be abnormal it was removed and the stump invaginated. The last four or five feet (1.2–1.5 m.) of ileum was inspected, but there was no evidence of a Meckel's diverticulum. The abdominal wound was closed in the usual layers without drainage.

Cultures were made from the appendix, the bile, and the gall-bladder wall. Each of these produced a rich growth of *Bact. paratyphosum* B. From the centre of the gall-stone no growth was obtained. Histologically, the gall-bladder showed a chronic

cholecystitis with ulceration. The stools have been examined many times since the operation, and on each occasion have been negative. The sample of urine taken one week after cholecystectomy was positive. The patient was found to have a cystitis, and was treated with acid sodium phosphate. The sample obtained a week later was sterile, and subsequent samples have also been sterile. A sample of serum sent two months after her cholecystectomy showed that the titre of her H agglutinins had dropped from the figure in October of 1 in 2,000 to 1 in 1,000, while the O titre had dropped from 1 in 1,000 to 1 in 500, and the Vi from 1 in 20 to negative.

Comment

The nurse made an uninterrupted recovery. Taking everything into account it has been considered safe to remove her suspension from the practice of midwifery, and she resumed duty as a district nurse in the early autumn. It is appreciated that a permanent cure cannot be taken for granted at this stage, although all the evidence points that way, and the case will be kept under close observation for a prolonged period. In this connexion, C. H. Browning and others (1933) advise post-operative examination of the faeces at frequent intervals for at least one or two years, and in a number of cases referred to in their memorandum examinations of the faeces continued for four or five years. It is interesting to note that this memorandum refers to seven cases in which the gall-bladder and appendix were removed. Of these, six were recorded as cures, and one as a failure.

The results of the surgical treatment in the present case appear to have been highly satisfactory, both as regards safeguarding the persons with whom the nurse may come into contact and, as regards the nurse herself, by preventing her from being permanently deprived of her means of livelihood.

Conclusions

Two main conclusions may be drawn from this case. (1) It supports the existing evidence that surgical treatment may succeed when medical treatment has failed. (2) During the operation for the removal of the gall-bladder the appendix should also be examined, and if its condition is in any way suspicious it should be removed.

Medical Memoranda

A Case of Rapidly Cured Hysterical Paralysis

In my experience various hysterical symptoms are often associated with emotional disturbances in auxiliaries and do not respond well to treatment. Frank conversion hysteria is, however, rare, so the following case, which was cured in one session, may be of interest.

Pte A, aged 20, arrived at the A.T.S. reconditioning centre with her right arm in a sling, saying that it was "useless". Two months before admission she had suffered from pain in the finger-tips followed by weakness and numbness of the fingers and hand, especially of the fifth digit. She went on leave and developed measles, so she was not seen by a medical specialist till she returned to her unit one month later. A diagnosis of ulnar neuritis and radiculitis was then made. She began to suffer from fainting fits and was admitted to hospital for 10 days. Feeling and strength partially returned, but a few days before her admission to the reconditioning centre, while at home on sick leave, she found it was quite "dead".

On examination she was seen to be in good general health and of average intelligence as shown by the matrix test. She was unable to move her right hand and fingers, and had to lift the hand out of the sling. Movement at the elbow and shoulder-joints was limited. There was no muscle-wasting or trophic skin changes, and all tendon reflexes were present and equal on the two sides. Muscle tone was good and the supinated forearm, when tossed from the couch, fell back in summation instead of pronating, as is usual in flaccid paralysis. Doubtful cutaneous hypo-aesthesia was present over the ulnar border of the hand and forearm.

In view of the history and findings a diagnosis of hysterical paralysis following neuritis seemed likely, and this was supported by testing the electrical reactions of the muscles. These were perfectly normal, except that the response of the posterior interosseal to faradic stimulation was weaker on the right than on the left. The girl, who was much impressed by seeing her fingers move in response to electrical stimulation, was informed that she had lost the strength in her hand when she had neuritis and had forgotten how to use it. She was told that she could now move her fingers and was

instructed to do so. She did, and after about ten minutes' explanation and persuasion she had regained practically full movements of the whole limb. The sling was removed and she was told to go and play the piano—a pastime of which she was very fond.

Apart from a certain initial clumsiness, which wore off with use, she made a complete and immediate functional recovery. No relapse and no further hysterical symptoms developed during the month she was at the reconditioning centre, or during the next two months, as reported by her unit M.O.

The patient was evidently a very suggestible girl, and her hysterical palsy appeared to have developed after her mother had told her, while she was on sick leave, that she had "creeping paralysis." She was delighted at finding that this was not so, and did not show any signs of anxiety reaction when her hysterical symptom was removed.

PATRIA ASHER, M.D., M.R.C.P.,
Capt., R.A.M.C.

Absence of C.S.F. after Head Injury

It is well recognized that low C.S.F. pressure readings are commonly found after head injuries, but we have not seen reference to or heard of a case in which no C.S.F. could be obtained.

CASE RECORD

A trooper aged 24 was admitted to hospital at 8 a.m. on Aug. 11, 1945, having been thrown from a horse at about 7.30 a.m. He had no memory of the accident, but was quite conscious on admission. The duration of unconsciousness probably did not exceed 20 minutes. The only external signs of injury were abrasions of the upper lip and root of the nose. He complained of some headache and giddiness, not of great severity at first, and he was simply treated as a case of mild concussion. On Aug. 14, however, he complained of very severe headache and pain in the back of the neck, and on examination was found to have marked neck rigidity and a positive Kernig's sign. There were no other C.N.S. changes. Temperature 98°, pulse 60, and respirations 20. In the meantime skilograms of the skull and cervical spine had been taken and no fracture or other bony lesion was seen. Lumbar puncture was done that morning, but no fluid was obtained, though the operator was quite sure he had entered the subarachnoid space. Later in the evening he was seen again and, there being no change in his condition, it was decided to defer further attempts to examine the C.S.F. till the next day.

On the morning of Aug. 15 he was still afebrile. He was a little slow mentally, the pulse rate was 56, and the meningeal signs if anything more pronounced. It was thought that these were due to blood in the subarachnoid space. Another lumbar puncture, however, again resulted in a dry tap. Accordingly, a few hours later a cisternal puncture was done—a first attempt being made in the lying position and the second while seated. Again no fluid was obtained, though the needle was certainly in the cisterna. While the cistern puncture was proceeding in the sitting position a sucking noise was heard as if air was being drawn through the needle. Almost at once the patient announced that his headache had become much easier, and it was found that the neck rigidity had partially gone. He was then taken to the x-ray department, and films showed that air had filled both lateral ventricles and was outlining the sulci on both sides—especially the right side—proving conclusively that the needle had been in the cisterna.

Thereafter he made an uninterrupted recovery. The headache did not reappear, and the neck rigidity had passed off entirely by Aug. 17. The pulse rate had by this time risen to over 70.

A further lumbar puncture on Aug. 22 resulted in a normal-looking fluid under pressure of 165 mm and containing 1 cell per cmm and less than 10 mg of protein per 100 ml. The Queckenstedt test gave a normal response. A lumbar puncture repeated on Aug. 31 showed a normal fluid under 160 mm pressure, with 5 lymphocytes and 1 red cell per cmm., 55 mg of protein per 100 ml., and a slight increase of globulin. Unfortunately the only blood-pressure recording was done on Aug. 16, and was 130/70; but the pulse volume was good throughout, and there is no reason to suppose that the blood pressure was abnormally low following the accident.

COMMENT

As there was manifestly no block to the circulation of C.S.F. it leaves no doubt that the volume of C.S.F. present must have been so small as to be unobtainable by lumbar or cisternal tap. The fact that air was sucked into the needle shows that there was actually a negative intracranial pressure. The explanation appears to be that the secretion of C.S.F. had ceased as the result of the trauma while its absorption proceeded normally. It has been suggested that the secretion of C.S.F. following head injury may be decreased as the result of cerebral anoxia due to depression of the respiratory centre, but there was never at any time in this case evidence of either cerebral anoxia or oedema.

It is possible that post-concussional headaches may be more often due to the decrease in volume and pressure of C.S.F., in contradistinction to the usually supposed increased pressure or cerebral oedema, than is commonly realized.

Reviews

PSYCHIATRIC OUT-PATIENT SERVICES

Neurosis and the Mental Health Services. By C. P. Blacker, M.D., F.R.C.P. Foreword by Sir Wilson Jameson, M.D., F.R.C.P. (Pp. 218. 21s.) London: Oxford University Press. 1946.

In this report to the Ministry of Health Dr. Blacker gives a very detailed account of a comprehensive survey of the psychiatric out-patient services of the country. He describes the number and the distribution of out-patient clinics and the work they are doing. He considers the question whether neurosis is on the increase, and concludes that no answer is possible yet, although absenteeism in factories, which has increased very much from before the war, is closely related to neurotic illness. There is a most interesting section on neurosis in industry, in which the opinions and the problems of industrial medical officers are discussed.

From the account of circumstances as they are Dr. Blacker passes to recommendations of what they should be, in both a short-term and a long-term programme. His proposals involve a great increase of the facilities at present available. For every million of the population 100 psychiatric beds should be provided outside the mental hospitals, the bulk of them being set apart for neurotic patients. These units might well be in general hospitals, and in hospitals with a medical school would be teaching psychiatric units. A considerable extension of out-patient facilities is proposed, for which bottlenecks in the training of psychiatrists, non-medical psychologists, psychiatric social workers, and occupational therapists would have to be dealt with. Child services are a first priority. For a population of a million there would be required ten child guidance centres, three child psychiatric clinics, a hostel for 50 unstable or difficult children, and a reception centre for the sorting and disposal of homeless and destitute children. The staff of mental hospitals must be increased and colonies for mental defectives provided on an adequate scale. A most interesting suggestion is that mental hospital psychiatrists should also be engaged in these other organizations, many of them being employed in a part-time capacity in all grades up to the highest—a measure which would help to attract the best men into psychiatry, and in the integration of psychiatry and general medicine.

The report is outstanding for its detailed factual basis and the clear vision of its proposals. It is to be hoped that it will meet with serious consideration by legislators.

PREVENTIVE MEDICINE

Preventive Medicine. By Mark F. Boyd, M.D., M.S. Seventh edition. (Pp. 591; illustrated. 27s. 6d.) Philadelphia and London: W. B. Saunders Company. 1945.

The seventh edition of Boyd's textbook on preventive medicine has been thoroughly revised and brought up to date. It is well produced, and documented with recent statistics.

The greater part of Dr. Boyd's book is devoted to the prevention of infectious diseases, individually rather than in the lump; and he deals with his subject in a sound, workmanlike manner. Under each heading he presents in succession the infective agent, the source of infection, the exit of the infective agent from the patient—and then follows the sinister career of that agent until it has established itself in another victim. This is a logical scheme, useful for quick reference. The dominant theme, and the author's special concern, lies in the study of methods of control. This matter is treated clearly and concisely, and the analysis of modern practice is valuable to the health officer and the general practitioner. Dr. Boyd has resisted the temptation to stray into the field of clinical signs and symptoms, and his book is all the better for this self-denying ordinance. It means that the student is able to concentrate his attention on strictly preventive methods.

"Public health" in the sense of environmental hygiene is introduced as part of the scheme for preventing infection rather than as a subject in its own right; and the final chapter, dealing with health administration, is hardly more than an apology for lack of time and space. The new material on nutrition and dietary deficiencies, however, is lively and interesting, and one feels that here again the author is on his own ground. He has

also provided an effective little study on demography, with special reference to statistics of sickness.

In spite of its condensation this book is a good, practical study of preventable diseases, infectious and other, and the doctor in everyday practice would profit by having it on his shelf, not too far away from his favourite guides in clinical medicine.

OPERATIONS SHOWN TO NURSES

Demonstrations of Operative Surgery for Nurses. By Hamilton Bailey, F.R.C.S. (Pp. 348; illustrated. 21s. plus 7d. postage.) Edinburgh: E. and S. Livingstone. 1945.

Mr. Hamilton Bailey was the originator of what may be called the demonstration type of book, in which common clinical signs, conditions, and manœuvres are simply described with copious illustrations, chiefly photographic, to enable the reader to form a clear visual impression comparable with that obtained from actual practice. In *Demonstrations of Operative Surgery for Nurses* he has maintained the level set in his previous books. Here the nurse will find straightforward accounts of what the surgeon is doing during the performance of most of the commoner operations, demonstrated by many different surgeons each taking an operation with which he is particularly familiar. To ensure uniformity of style the descriptions have been carefully edited by the chief author, and, as he says in his preface, should be easily within the grasp of the junior probationer.

The illustrations, many in colour, constitute the outstanding feature of the book. There are over 500 of them, carefully chosen and beautifully reproduced. A minor feature deserving a word of praise is the introduction of footnotes to tell the nurse who the surgeons are whose names appear in the text—thus when a de Pezzer catheter is mentioned the footnote reads: "Dr. de Pezzer, Assistant to Prof. Guyon, Necker Hospital, Paris. Invented the de Pezzer catheter in 1885." Too brief to be called biographies, these notes we nevertheless feel are both attractive and useful.

The general production of the book is up to Messrs. Livingstone's usual high standard.

REGIONAL EPIDEMIOLOGY

Global Epidemiology. A Geography of Disease and Sanitation. By James Stevens Simmons, M.D., Tom F. Whayne, M.D., Gaylord West Anderson, M.D., Harold MacLachlan Horack, M.D., and collaborators. Volume 1. Part 1, India and the Far East; Part 2, The Pacific Area. (Pp. 504-30s.) London: William Heinemann.

This book is based upon data collected for the use of the United States Armed Forces in the late war. Vol. I covers India, the Far East, and the Pacific area. Information is given under a series of headings. First, the geography and climate of the region under study are considered. Next, under the heading public health, one has an account of the organization (if any); then, under subheadings, accounts of water supplies, sewage disposal, insects and other animals of medical interest, poisonous plants, food and dairy products. The next main heading is medical facilities, with subheadings for hospitals, medical personnel, and medical institutions. Then one has diseases, under five subheadings—viz., diseases spread chiefly through the intestinal tract, diseases spread chiefly through the respiratory tract, diseases spread chiefly by contact, diseases spread by arthropods, miscellaneous diseases. There are a short summary and a bibliography.

From the point of view of the general reader, the descriptions of small islands—for instance, Pitcairn Island and Easter Island—are more interesting than those of vast territories, such as Australia or China. The volume should be a useful introduction to more detailed studies by students at home, who will find the bibliographies helpful.

Notes on Books

Art versus Illness, by ADRIAN HILL, is published at 10s 6d. by George Allen and Unwin. The author was a patient in a tuberculosis sanatorium and found that his morale was failing with the long days and weeks of inactivity. Thanks to his capacity for artistic expression he was able to overcome this and achieve the necessary mental attitude towards recovery. He succeeded in interesting his fellow-patients both in the appreciation of pictures and in learning to draw and paint themselves. He was able to find some degree of artistic talent in almost all those whom he approached, and claims that by

fostering this talent and arousing their interest in art he did much to hasten recovery. The present book is a useful guide to this particular form of occupational therapy. Not only will it prove of great service to those who are already artistically inclined, but many who have no idea that they possess such gifts may be found to have them and will correspondingly benefit by their exercise. The importance of treating the mind as well as the body, especially in chronic illness, is being increasingly recognized, and Mr. Adrian Hill's book admirably describes one method of achieving this end.

The St. John Ambulance Association (St. John's Gate, Clerkenwell, London, E.C.1) has issued as a 6d. pamphlet (post free 7d.) a Supplement to the 39th edition of *First Aid to the Injured*, of which 150,000 copies had been printed by the end of last year. A full revision of the main textbook will be undertaken as soon as practicable, but in view of the suggestions and criticisms received since the last edition appeared in 1937 and the knowledge gained in certain aspects of first aid by the experiences of the war, it has been decided to issue this supplement, which is partly a revision of the sections dealt with and partly additional matter.

The National Council of Social Service has published a handbook of advice and information for those who wish to give aid and comfort to old people. It has been compiled by the National Old People's Welfare Committee and gives a practical lead to organizations and private citizens on one of the subjects of to-day. In view of the inevitable increase in the proportion of old people in our community, it is urgent that public opinion be educated about their needs. It is to local and regional old people's welfare committees that the authors of this pamphlet look for co-operative social action to ensure the visiting of lonely old persons (whether living in institutions or in their own homes); to provide voluntary residential homes for able-bodied old people (perhaps by means of a housing association); to organize clubs in which men and women can find fellowship and recreation; and to build up a communal meals service or a scheme of home helps. Practical advice and information on all these are given. *Old People's Welfare* is obtainable from the N.C.S.S., 26, Bedford Square, London, W.C.1, price 1s. 6d., post free.

The October-November, 1945, issue of *L'Architecture Française* (No. 51-52) is devoted to hospital construction and is published from 41, Boulevard de Latour-Maubourg, Paris, Ville, price 150 francs. It opens with articles on "cabinets de groupe" and on the place of the hospital in a general health service by Dr. Marc Nédélec, followed by one on new tendencies in British hospital organization by Dr. R. F. Bridgman. Descriptions of new hospital buildings in Melbourne and in Sydney and the hospital at Haifa, Palestine, come next; then a long article on hospital architecture in the United States, and another on the projected medical centre at Lille. Michel Roux-Spitz writes on the renaissance of medical architecture, and A. Laborie on the hospital centre for Niort. The whole of this special number is freely illustrated with reproductions of photographs, plans, and diagrams.

Preparations and Appliances

A PLASTIC SPLINT FOR OPONENS POLLICIS PARALYSIS

MR. JOHN A. CHOLMELEY, M.B., B.S., F.R.C.S., resident surgeon, Royal National Orthopaedic Hospital, Stanmore, writes:

The efficient splinting in a case of opponens pollicis paralysis has always been a difficult procedure, as witness the variety of splints designed for this purpose, such as that of Miss Forrester-Brown and that described by Mr. J. Russell Napier (1946). In cases of paralysis following anterior poliomyelitis it is not infrequently found that residual weakness or paralysis of the opponens pollicis remains; to splint this adequately, to prevent stretching of the weakened muscle, and to improve the efficiency of the hand has been to me a difficult problem, the splint must remain in position under all conditions, it must be light and preferably inconspicuous—particularly when the paralysis is permanent—and it is desirable that it should be washable.

For some while the application of plastics to splints has been exercising our minds at the Country Branch of the Royal National Orthopaedic Hospital, and the results of the work of Scales and Herschell (1945) suggested to me that "perspex" was a suitable material from which to make an efficient splint in opponens pollicis paralysis. The design that I outlined was that of a band encircling the hand with a tongue passing between the thumb and index finger to keep the thumb in opposition whatever other movements were carried out by the wrist and fingers. It has been found possible to make such a splint of perspex or P.V.C. (polyvinyl chloride); in the case of perspex the usual thickness required is 1/8 in. (3 mm.) or 3/32 in. (2.5 mm.) and the P.V.C. is approximately 3/32 in. thick; both materials have sufficient elasticity to enable the splint to be a close fit (see Figs. 1 and 2) and yet quite easy to put on, but the

perspex is rather more rigid of the two; thus when the rest of the muscles are strong, particularly in an adult, perspex is slightly preferable. The splint is washable, permits free movement of the wrist, fingers, and the terminal phalanx of the thumb; other movements of the thumb are permitted but are somewhat restricted. When wearing the splint the patient can wash and dress himself, and it does not interfere with writing or using a typewriter. The only objections so far found in the materials used are that the present perspex obtain-

FIG. 1

FIG. 2

able is a little too brittle to stand very rough usage and occasionally splints made of P.V.C. have cracked; however these disadvantages can be overcome and are easily outweighed by the efficiency and comfort of the splint.

I should like to express my gratitude to Mr. J. T. Scales and Mr. W. Herschell for their help, and to the latter particularly for his patience in carrying out my suggestions.

COMPRESSION BANDAGES FOR VARICOSE ULCERS

Dr. R. R. FOOTE (London, W.1) has had made two special bandages for the compression treatment of conditions associated with varicose veins. One is a two-way stretch bandage easily applied and removed; the other is an elastic supporting bandage. Details of both may be obtained from the makers, John Bell and Croyden, Wigmore Street, London, W.1.

EMERGENCY GUARANTEE FUND

As announced on another page, the Council of the British Medical Association has decided on the establishment of a new Emergency Guarantee Fund so that the profession may be financially armed in any conflict it may have with the Government over the National Health Service Bill soon to be laid before Parliament. So that any action the profession may take should not be hampered by lack of means to back it up, it is proposed that every medical man and woman on the *Register* should stand guarantor for as much as he or she can afford—but generally not less than £25. It may be that no one will be called upon to part with his money, but if the profession is to be united in action on a policy which commands the whole-hearted agreement of the majority, then it should be prepared to spare no means to make its action effective. Should there be fundamental disagreement with the principles underlying the proposals the Minister puts before Parliament, then the medical profession, constituting the key workers in the new service, will have to strive hard so to influence public opinion that the pressure of this upon Parliament will lead to the modification of those elements in the Bill to which soundly rooted objection may be taken.

The cost of this campaign will be borne from existing resources. But should Parliament prove obdurate and refuse to modify proposals in the Bill which the profession might consider to strike at the essential freedoms of medicine the doctors of this country might have to decide not to work in the new service. Such a decision would not be taken lightly, nor would such a decision mean that medical men would withhold their skill from patients in need of it. It would mean simply that the majority of doctors would continue to serve their patients outside and not inside the new service. If this happened vastly greater resources would be needed, and it is with this possibility in mind that the Council has caused the new fund to be established. It is earnestly to be hoped that everyone, whatever his political views, will make the individual guarantee asked for.

To be forearmed is to be prepared for the fight if there is to be one, and the Emergency Guarantee Fund is being established for this purpose. Whether a fight will be necessary will not be known until the contents of the Bill are revealed, until it has been possible to formulate the attitude of the doctors of this country to them, and until the final answer of Parliament is known. Each doctor will have to make up his own mind, and the task of the British Medical Association and the Negotiating Committee will be to discover what the consensus is, and then to decide in the light of this what action to take to see that the views

of the majority prevail. Although the present Government has a substantial balance of votes in the House of Commons it would presumably be reluctant to try to coerce the medical profession to accept a form of service which it considered incompatible with its honour and real interests. If the new health service is to take proper shape and is to provide for the medical needs of the people of Great Britain the Government must have the willing co-operation of the medical men working in it. It is to be hoped that the Bill will be so framed as to make this possible, and so avert a costly and bitter struggle which, whatever the outcome, will leave behind it a sense of frustration and discontent.

CUSHING'S SYNDROME

Since Cushing first described the symptom complex associated with basophil adenoma of the anterior pituitary a number of cases have been recorded with the same symptoms but with no pituitary tumour. Such cases are classified as Cushing's syndrome as distinct from Cushing's disease. A common feature of the disease and of the syndrome is cancer, adenoma, or hyperplasia of the adrenals, and many authorities¹⁻³ now regard adrenal hyperfunction as the primary cause of the condition, even if hyperplasia is not always demonstrable. Albright,² who reviews the means by which adrenal overactivity could produce the predominant symptoms, regards the cardinal feature of the syndrome as tissue deficiency, evidenced by thin skin, weak muscles, osteoporosis, and easy bruising—symptoms usually associated with a tendency to insulin-resistant diabetes and increased 17-keto-steroid excretion. His first hypothesis was that the over-secretion in the adrenal cortex was particularly of those hormones affecting sugar metabolism, so that there was increased gluconeogenesis, leading to the diabetic tendency and loss of tissue. Treatment with androgens was therefore begun to produce nitrogen retention and the deposition of muscle tissue. The results were successful: the patients became stronger and heavier, and their nitrogen, calcium, and phosphorus balances became positive. That this was due to the deposition of normal tissue was shown by the close agreement between the theoretical phosphorus retention based on the calcium retention ($\text{Ca}:\text{P}$ of bone=2.23) and nitrogen retention ($\text{N}:\text{P}$ of soft tissue=14.7) and the phosphorus retention as measured. These beneficial effects of androgen are confirmed by Perloff, Rose, and Sunderman,⁴ although they find the high nitrogen retention initially produced maintained only partially during long-continued androgen therapy.

If Albright's theory were true there should be a negative nitrogen balance with an abnormal tendency to ketosis in Cushing's syndrome, and it might be expected that uncontrolled diabetics would develop similar symptoms; but this does not happen. The nitrogen excretion under conditions of minimal nitrogen intake should still be high; in fact it is not. To circumvent these objections Albright suggests

¹ Anderson, E., Haymaker, W., and Joseph, M., *Endocrinology*, 1938, 23, 398.

² Albright, F., *Harvey Lectures*, 1943, 38, 123.

³ Kepler, E. J., *J. clin. Endocrinol.*, 1945, 5, 70.

⁴ *Arch. intern. Med.*, 1943, 72, 494.

that the hormones of the adrenal cortex affecting sugar metabolism do not stimulate catabolism but interfere with anabolism. This would explain the diminished nitrogen output in conditions of diminished intake. The author follows others in believing that there are two hormones or groups of hormones produced by the adrenal cortex—one group affecting sugar metabolism, the other growth and nitrogen metabolism (briefly referred to as S and N hormones). On the basis of various clinical and experimental findings Albright suggests that the N-hormone production is raised only slightly in Cushing's syndrome and is indicated by the increased 17-ketosteroid excretion. The rise is regarded as compensatory, and it can be reduced by giving methyl testosterone (which is not itself excreted as ketosteroid). He thinks the adreno-genital syndrome is due to an increase in N-hormone production.

Albright is well aware how many unproven links there are in his chain of deduction, and his theory is only tentative. It offers no explanation of the hypertension, and would lead one to expect changes in blood electrolytes the opposite of those in Addison's disease; but such changes have been found in only a small proportion of cases.⁵⁻⁷ However, the new theory does at least give rise to a new outlook on clinical cases and suggests new lines of investigation. This is of especial importance in such a comparatively rare disease, where large series of cases can be studied only from reports which often fail to provide the one essential detail. Albright's theory leaves the explanation of basophil-cell hyalinization open to debate, for this change in the anterior pituitary is to-day the most constant pathological finding in Cushing's syndrome, as it was when Crooke⁸ originally described it. Thompson and Eisenhardt⁹ found hyalinization present in the hypophyses in 58 of 63 cases, and the remaining 5 cases were doubtful examples of the syndrome. Does the change in the basophil cells represent a stage of cell death or a phase of cell activity? In either case it can be regarded as an effect of adrenal overactivity and at the same time as the immediate cause of at least some of the symptoms of Cushing's syndrome. If the hyalinization is degenerative then one may view it, as Kepler³ does, as a sign of compensatorily depressed corticotrophin secretion; but the basophil cells do not secrete one pituitary hormone alone, and it is unlikely that a profound change in corticotrophin secretion would leave the secretion of the other hormones unaffected. Hence the symptoms caused directly by adrenal oversecretion may be supplemented by other secondary effects. McLetchie¹⁰ believes that basophil-cell overactivity is the essential lesion in Cushing's syndrome (or disease), and that the hyalinization is a consequence of this; but as he regards the adrenal cortex and the basophil cells as members of a complex in which overactivity of either leads to overactivity of the other his interpretation does not differ widely from theories which hold an adrenal cortical lesion to be the primary cause.

SYNERGISM BETWEEN ADRENALINE AND ACETYLCHOLINE

The pharmacological effects of adrenaline and acetylcholine have a special interest because it appears to be a general law that all their sites of action are supplied with nerves capable of releasing the appropriate substance locally. New pharmacological discoveries about them, thus lead almost inevitably to new physiological knowledge. The actions and interactions of these two substances have been much studied in recent years and much new information has been obtained, largely as a result of a brilliant series of papers from the pharmacological laboratory at Oxford. An authoritative review¹ of this work by Prof. J. H. Burn will be widely welcomed.

The actions of acetylcholine can be divided into muscarine actions and nicotine actions. Most, though not all, muscarine actions resemble the effects of stimulation of parasympathetic nerves. They are antagonized directly by atropine, and indirectly by the opposite effects produced by the injection of adrenaline or by stimulation of adrenergic nerves. This much is simple and familiar, but the nicotine actions are more complicated. These are mostly actions on nerve cells or voluntary muscles, causing the initiation of impulses which are conducted over the cell with the characteristic rapid electric changes. Small doses of acetylcholine produce these impulses; larger doses eventually depress them. Prostigmin inhibits the destruction of choline esters, so that small doses of acetylcholine act as if they were larger than they really are. The stimulant action of very small doses is thus increased, and that of rather larger doses may be changed to inhibition. The action of adrenaline is superficially similar but fundamentally different. Low concentrations of adrenaline increase the stimulant action of small doses of acetylcholine, and higher concentrations of adrenaline antagonize them. These two actions may be seen as two phases in the effect of a single dose.

The synergistic action of small doses of adrenaline and acetylcholine is of fundamental interest. It has been most carefully studied in perfused sympathetic ganglia. Using this preparation E. Bülbring found that low concentrations of adrenaline increased the effect of preganglionic stimulation or of the injection of acetylcholine. She also found that the ganglion itself liberated a small amount of adrenaline when the preganglionic nerves were stimulated, in addition to the acetylcholine whose liberation was demonstrated 12 years ago. This surprising fact suggests that adrenaline, as well as acetylcholine, may play an essential part in the action of the ganglion.

Adrenaline, either injected or liberated by adrenergic nerves, also has various actions on voluntary muscles and nerves. It increases the action of acetylcholine on denervated muscles; it improves neuromuscular transmission when this is diminished by fatigue; it actually improves transmission along the trunk of a nerve. This last fact was discovered in perfusion experiments in which the nerves gradually lost their action on the muscle unless they were stimulated near the muscle, but regained it under the action of adrenaline. It was confirmed by the observation that adrenaline increases the action potentials in the nerve itself when the stimulus is submaximal. Even this effect may be an example of synergism between adrenaline and acetylcholine if the theory that acetylcholine plays a part in the transmission of impulses along a nerve is confirmed. These experiments provide part, at least, of the explanation of the action of adrenaline in diminishing muscular fatigue, and of the action of ephedrine in myasthenia gravis:

ephedrine presumably acts by preserving the natural adrenaline of the body from destruction. Similar effects have been discovered in the spinal cord. Bülbbring and Burn perfused a dog's spinal cord with blood, and showed that the arterial injection of acetylcholine caused contraction of voluntary muscle due to impulses passing down the nerves, provided that adrenaline was present in the blood supplying the spinal cord. If there was no adrenaline there was no effect.

The explanation of these synergistic effects of adrenaline and acetylcholine is unknown. They are not due to an effect of adrenaline on cholinesterase. They are probably not due to an action on the blood supply to the muscles and nerves. It is suggested that adrenaline may improve the access of acetylcholine to its site of action by altering the permeability of a hypothetical membrane, but there is no direct evidence for this theory.

It is not possible to give here more than a brief summary of some of the more striking facts. It is clear that pharmacology has added an important new chapter to our knowledge of the workings of the body.

MORTALITY FACTORS IN ACUTE APPENDICITIS

So long as patients continue to die from appendicitis—and Prof. Grey Turner¹ reminded us in 1938 that about 3,000 people die every year from acute appendicitis in the United Kingdom—reports of appendicitis will continue to be important, but they will be important only if the results are measured against a rigid statistical yardstick. Hoerr² has published from the Peter Bent Brigham Hospital a long series of cases of acute appendicitis from which several interesting and a few important findings emerge, all bearing the hallmark of statistical significance. The series includes 2,195 case records from the period 1913–40, with a total mortality of 4.6%. None of the patients was under 12 years of age.

The first surprising feature is that there has been no significant improvement in mortality since 1913, in spite of improved technique, a better understanding of gastro-intestinal physiology, and an appreciation of the importance in peritonitis of gastro-intestinal siphonage and fluid balance. No reduction of mortality followed the introduction of sulphonamides. In the series there were 100 deaths; two of these occurred in the operating theatre, and 18 were due to extra-abdominal causes. The remaining 80 cases, in which death was due to unchecked appendicitis or its immediate abdominal complications, are specially studied. Only 13 of these 80 patients were operated upon within forty-eight hours of the onset of the disease; in 53 the appendix had perforated into the general peritoneal cavity, in 14 there were localized abscesses, and in 13 the appendix was unruptured. In 22 patients the cause of death was progressive peritonitis, and in 15 patients it was residual abscess—multiple in 11 cases, and drained at a secondary operation only in 5. The other abdominal causes of death were ileus, mechanical obstruction, pyelephlebitis, pyaemia, and anaesthetic death at a second operation. While no overwhelming advantage seemed to be derived from the McBurney incision, there was a significant difference in its favour in all cases except those of localized abscess, when in any event the best incision is that which directly overlies the abscess.

When the fatality rates of drained and undrained cases are compared no useful information is obtained, since drainage is performed as a rule in the more serious cases. Such a comparison does, however, prove useful in one respect: the fatality rate in the undrained cases

of appendicitis *with* perforation (2.4%) was less than the fatality rate in the drained cases of appendicitis *without* perforation (3.1%). Here is strong justification for the modern trend towards closure without drainage after removal of the unruptured or the recently ruptured appendix.

Hoerr's analysis serves as a warning to the surgeon against the complacent assumption that death from acute appendicitis can always be ascribed to lateness of operation; those deaths which were due to failure to drain a residual abscess argue, in these cases, a fault in post-operative management, and certain of the other deaths, Hoerr avers—and notably the 10 due to post-operative intestinal obstruction—might have been avoided.

THE LANCAS TUBERCULOSIS SCHEME

It is an achievement in any branch of medicine for one person to look back over a continuous record of success lasting 33 years in dealing with a particular problem. For long the Lancashire Tuberculosis Scheme has been synonymous with the name of Lissant Cox, and his final report, though abridged from the elaborate compilations of pre-war days, gives the material for appreciating this first-class clinical and administrative organization. After two world wars and a "financial blizzard," the Lancashire scheme is more comprehensive than ever before, and in 1934 over 30% of pulmonary cases on the register had received some form of thoracic surgery. Divided into five large areas, each with over a quarter of a million people, and now including as satellites Blackburn County Borough and the Isle of Man, the Lancashire scheme is founded on a series of tuberculosis hospitals, to which dispensaries and social services are attached. Dr. Lissant Cox points out that the White Paper proposals tend to follow a principle which has always been maintained in Lancashire—namely, that a tuberculosis officer should be at the same time hospital physician, dispensary consultant, and director of social work among his patients. Certainly the Lancashire results justify this conception of united tuberculosis work.

The war has left from 12 to 15% higher incidence of pulmonary tuberculosis over 1938, with no smaller rise in non-pulmonary disease, but these figures are less severe than in other areas. Maintenance allowances (266/T) are considered successful, so far as they go, but need improvement for chronic patients and extension to non-pulmonary disease. Dr. Lissant Cox's report is no exception to others when it speaks of the shortage of staff, both nursing and domestic, and the resulting long waiting list of over 1,000 patients. A deputation to the Ministers of Labour and of Health failed to produce an improvement, and the position is even more serious than last year, showing now a deficiency of 28%. In this connexion it is satisfactory to notice that progress has been made with a systematic supervision of nurses' health: x-ray photograph, Mantoux testing, records of weight, etc., are now a routine in all the Lancashire sanatoria, and the general improvement in the nurse's environment is being accelerated.

One most interesting feature of the report is a note of a case of avian tuberculosis in a human being, as discovered by Dr. F. C. S. Bradbury, who typed the culture in his own laboratory. This is the first such instance to be reported in this country of what must be a very rare condition. Bradbury suggests that typing of culture material should be developed further to pick up the odd avian case. This would be interesting from a research point of view, though it is at present difficult to see what bearing it would have upon clinical treatment. The Lancashire scheme costs the ratepayers over a quarter of a million pounds, or the equivalent of nearly sixpence in the pound.

¹ *British Medical Journal*, 1938, 2, 691.

² *Surgery*, 1945, 18, 305.

Lancashire is fortunate in having chosen as successor to Lissant Cox Dr. Bradbury, who unites sound clinical judgment with an extensive knowledge of the bacteriology, science, and mathematics of his calling. He becomes consulting central tuberculosis officer—a status slightly varied from that of his predecessor, as Dr. Bradbury is now administratively responsible to the county medical officer. Dr. Lissant Cox may look back with satisfaction upon his life's work, and the success of the Lancashire scheme is due chiefly to his human qualities, his correct choice of men, his enthusiasm.

NEONATAL MORTALITY IN ABERDEEN

In recent years almost half of the neonatal mortality has been due to prematurity, and it is obvious that the causes must be found and eliminated if any considerable reduction in infant mortality is to be achieved. In a recent paper Prof. Baird¹ examined the probable causes of prematurity and the influence of social and economic factors. The material consisted of hospital and nursing-home cases in the city of Aberdeen. The classification of prematurity was by weight and included all infants of $5\frac{1}{2}$ lb. (2.5 kg.) or less irrespective of the length of gestation. It is difficult to arrive at the incidence of prematurity in the general population, since the lying-in hospitals, which supply most of the data, do not give a cross-section of the community; comparison between hospitals is not less difficult, as the emergency cases admitted vary in number and have a prematurity rate of about four times that of booked cases. During the six years 1938–44 8,808 booked cases were treated in Aberdeen, and in 738 instances the labour resulted in a premature baby—i.e., 8.4% of the total deliveries. In 51.9% of the cases the cause of prematurity was unknown; in 16.1% it was due to eclamptic toxæmia, and twin pregnancy accounted for 12.4%. Of 1,920 births in nursing homes and specialists' practices 91 (4.8%) were premature. The mortality among the live-born prematures was 26% in the hospital series and 12% in the other group. The difference in survival rate is attributed by the author to the greater vitality of the infants in the latter group compared with the former, and not to differences in nursing or medical care. Eclamptic toxæmia, the most frequent obstetrical condition associated with prematurity, was twice as common in the poorer hospital group as in the well-to-do specialist group; the percentages were 8.5 and 4.4 respectively. The stature of the mother in the better economic group was greater than in the hospital group, and in both groups there was a correlation between height of mother and weight of baby. Caesarean section appears to be related to stature; this mode of delivery was practically confined to very short women. Forceps delivery does not appear to be related to stature, and was over three times more common in private practice than in hospital experience.

The recent fall in the stillbirth rate may to some extent be due to better management of pregnancy and labour, but Prof. Baird thinks it is more likely to be associated with the better nutrition of the mother. The fall in the neonatal mortality in Aberdeen—the rate in 1944 was 83% of that in 1938—was due to the large reduction in prematurity and congenital debility. Infection as a cause is still as common, but there has been an increase in other causal conditions. For example, the frequency of congenital malformation as a cause of neonatal mortality was 195% of the pre-war level. Prof. Baird considers that the diminution of neonatal mortality in Aberdeen during recent years is mainly due to the better health of the mothers as a result of improvements in diet. But he points out that it

is difficult to produce direct evidence about experiments in human nutrition, as only small numbers can be successfully dealt with in detail. The issue of supplements does not appear to have been popular; the author stated, "In many cases, however, not more than 30% of the expectant mothers take up these vitamin preparations"—that is, the orange juice, cod-liver oil, and vitamin A and D tablets provided in antenatal clinics.

EVOLUTION OF VIRUS DISEASE

F. M. Burnet's Dunham Lectures at Harvard have been published as a Harvard University Monograph entitled *Virus as Organism*.¹ They combine with instructive and well-documented fact a good deal of very interesting speculation. The author concludes in the first place that viruses must be regarded as micro-organisms, and accepts the hypothesis originally advanced by Laidlaw that they are degenerate forms of what once were larger and more independent species, probably bacteria. He next looks for the ultimate source of almost all human virus infections in diseases of animals, pointing out that man has been sufficiently gregarious for continued spread to be possible in the human host only for a few thousand years. The first known appearance in man of many virus diseases is much more recent than that: psittacosis, St. Louis encephalitis, and others have attacked man only in the present century. Derivation from animals is perhaps most clearly seen in yellow fever, the jungle reservoir of which has been brought fully to light only recently. It is tempting, since Theiler's discovery of a similar infection in mice, to assume a rodent source for poliomyelitis. The probable history of these and other virus diseases is the major theme of these lectures, but involved with it are other aspects of the host-parasite relationship. Of particular interest is a critical analysis of the epidemiology of influenza. Burnet is not encouraging on the subject of influenza vaccines; during propagation in the laboratory the virus passes from the O to the D phase, a change accompanied by a demonstrable reduction in pathogenicity, and "one has an uneasy feeling that perhaps all our current influenza laboratory work is being done with something which has ceased to be the pathogenic virus with which we ought to be primarily concerned." There also appears to be some element in influenza immunity other than the antibody content of the blood, and hence incapable of assessment.

The general impression produced by this brilliant survey is on the whole rather alarming. We are singularly defenceless against many of the viruses, and, despite the accumulated data of many years of study and all the deductive and imaginative treatment which Burnet can bring to bear on them, we scarcely know the first thing about why a virus may suddenly increase the scope of its activity. Whatever factors may be concerned, they have certainly operated under the conditions in which we are now living, and further developments may be expected, whether in the greater prevalence of recognized virus infections or in the appearance of new ones.

Prof. Adolf Lorenz, the famous Viennese orthopaedic surgeon who introduced the bloodless method of reducing congenital dislocation of the hip-joint by forcible manipulation, has died in his 93rd year.

Dr. W. S. A. Griffith, consulting physician-accoucheur to St. Bartholomew's Hospital, has died in his 92nd year.

RECURRENT DISLOCATION OF THE SHOULDER

THE JOHANNESBURG STAPLE DRIVER

BY

Sir HENEAGE OGILVIE, M.Ch., F.R.C.S.

Late Consulting Surgeon, East Africa Force

In the rejoicings over victory the first successful campaign in the cause of freedom, and one of the most dramatic military feats in the world's history, is seldom remembered. At the end of January, 1941, the East Africa Force, under Sir Alan Cunningham, forced the passage of the Juba River on the Kenya frontier. In little more than two months they advanced nearly two thousand miles over some of the most difficult country in the world—the waterless and roadless deserts of Somalia and the mountains, forests, and precipitous gorges of Abyssinia, and defeated an army enormously superior in numbers and equipment.

The East Africa Force had no British units and only a few individual officers from Britain. The soldiers were chiefly Africans, men from the Gold Coast, Sierra Leone, Nigeria, and the East African Territories, under European officers—regular soldiers or settlers. The specialist services—engineers, artillery, air corps—were for the most part South African, and South Africa also provided the spearhead of the infantry and the bulk of the medical services, to which units from Southern Rhodesia, Kenya, the Gold Coast, Nigeria, Zanzibar, Uganda, and Tanganyika were added. A more magnificent body of men it would be hard to find. The African as a soldier displays a courage that no danger can daunt and a cheerfulness that no discomfort can damp. The European bred in Africa, like his cousins in Australia and New Zealand, and his compatriots the brown trout when transplanted to the same territories, seems to develop a size, physical beauty, and stamina exceeding that of his parent stock. These men were tough; and almost the toughest thing about them was their habit of playing rugby football on fields like stretches of gravel littered with large stones. It is little wonder that habitual dislocation of the shoulder, which Bankart pointed out many years ago is seen chiefly in epileptics and rugby footballers, seemed almost an occupational injury among South Africans and Rhodesians in the Force. The number I saw was considerable. The number requiring operation during the year and a half that I was in the command was about a dozen.

This note is prompted by Surg. Cmdr. P. B. Moroney's description in the *British Medical Journal* of July 28, 1945 (p. 122), of a technique for drilling the glenoid in Bankart's operation. As he states, the essential lesion in habitual dislocation of the shoulder is a detachment of the anterior half of the glenoid ligament, leaving the glenoid surface a shallow oval facet on which the humeral head rests insecurely. The treatment is therefore replacement and reattachment of the glenoid rim. Clairmont's operation is based on faulty pathology, but it often works because of the mass of fibrous tissue which it wraps round the joint. Nicola's operation, limiting movements which should be free by an intra-articular ligament that should not be there, restrains movement and dislocation only till the ligament saws off, when the dislocation returns but not all the movement. The various bone-graft operations, judging from the skiagrams I have been shown, depend on the production of a massive osteoarthritis for their success. Glenoid reconstruction has not failed in my own cases of dislocation or those I saw in Johannesburg, and it leaves a full range of painless movement.

Surg. Cmdr. Moroney's apparatus seems a complicated way of doing a fixation that can be performed in a few minutes with the Johannesburg staple driver illustrated. This model was presented to me in 1941 by Mr. A. D. Polonsky, one of the brilliant group of orthopaedic surgeons working under F. P. Fouché at the Johannesburg General Hospital and in the traumatic service of the Mines Hospital, and was, I believe, modified by him from the model originally designed by Allen of Durban, and made in the workshops of the Department of Mines. It has been copied by Down Bros. (Fig. 1).

The application of the instrument needs no description. I used two or three staples to fix the glenoid rim, and another to reattach the coracoid. My post-operative skiagrams are all in Kenya, but the outline sketch (Fig. 2) will illustrate the position of the staples.

FIG. 1

FIG. 2

N.B.—I have heard from Mr. Fouché that a later model, in which the staple is held in its socket by a hook, is now in use in Johannesburg.

WARTIME ACTIVITIES OF THE HEALTH ORGANIZATION OF THE LEAGUE

A special number of the *Chronicle of the Health Organization of the League of Nations*, the publication of which was suspended in May, 1940, has been issued¹ describing the work and difficulties experienced by the Health Organization during the past years. The return of officers to their own national service had reduced the staff of the Health Section to two doctors by the middle of 1940, and as the war went on the difficulty of communications prevented headquarters from obtaining advice from the members of the Health Committee and its technical commissioners. The result of this isolation was that the Health Section was increasingly compelled to rely on its own resources. The publication of the *Weekly Epidemiological Record* was never suspended during the war, though its field of activity was restricted. Before the war the Epidemiological Intelligence Service received data regarding infectious diseases and demographic statistics from every country in the world, with the exception of the Soviet Union, and from most large towns. From 1940 onwards no information was forthcoming from the zones of military operations, and the spread of the war to America and the Far East caused the League's Epidemiological Service to concentrate on Europe. The service was successful in obtaining data respecting epidemics and mortality from belligerent, occupied, and neutral countries; the only exceptions were the eastern front and Albania, Serbia, and (at some periods) Greece, the latter countries having been deprived of postal services with the outside world.

Biological standardization, a special feature of the work of the Health Organization, proceeded satisfactorily during the war. The Danish State Serum Institute at Copenhagen, which was entrusted with the distribution of international standard-

¹ Obtainable from Allen and Unwin, 40, Museum Street, London, W.C.1.

of sera, was cut off from many countries by the invasion of Denmark in April 1940. The Medical Research Council was approached and agreed to supply from the National Institute at Hampstead international standard sera to the laboratories in the countries which were no longer able to obtain them from Copenhagen. The National Institute had previously been responsible for the standardization of vitamins, hormones and certain medicaments. On the Health Section's initiative an international conference on the standardization of penicillin was convened in London in October, 1944, under the presidency of Sir Henry Dale. A similar field of work, the unification of the national pharmacopoeias was continued throughout the war.

Although the pre-war work was continued so far as possible and despite staff shortages particular problems arising directly out of the war were undertaken by the Health Organization. These problems covered a wide range in the medico-social field. Information about the food ration before and during the war in occupied countries, the types of vitamin deficiency disease that were most to be feared and other data on possible post-war requirements were supplied to the Inter Allied Bureau set up in London in 1942. In 1943 the Health Section co-operated with UNRRA by lending a staff to provide an epidemiological intelligence service in Washington; this staff was later taken over by UNRRA. A polyvalent glossary of communicable diseases, giving terms employed to designate them in twenty-four European languages, was prepared for the International Red Cross.

The report shows that despite adverse conditions and reductions in resources of the Health Section its pre-war activities were maintained though modified by circumstances in some instances and that the organization was successful in adapting itself to the difficulties and demands that arose out of hostilities and was able to perform very useful service.

TRAINING OF GENERAL PHYSICIANS

In October, 1945 the Council of the Royal College of Physicians of London appointed a committee of nine Fellows "to consider the question of the training required for general physicians and to report back to the Council." The committee having fulfilled its terms of reference the Council submitted the following report to the Comitia held on Jan. 31, which approved it.

Criteria for Consultants

The Council considered the criteria for consultants which had already been approved by the three Royal Colleges.

1 Consultants must have received their training at an approved hospital. Each College shall approve hospitals as suitable for training in its own branch of the profession and recognition shall be granted by the Standing Joint Committee on the nomination of the individual College concerned.

2 Consultants shall have a minimum of five years' approved training and experience after qualification.

3 Consultants must hold an approved higher degree or diploma.

4 To be approved as a consultant a candidate must hold or have held a recognized appointment to a hospital.

5 Consultants must not engage in general practice.

The Council approved them in principle as applying to general physicians but pointed out that training might be undertaken at more than one hospital. It also agreed that the consultant should have a minimum of five years' approved training and experience after qualification. This should be held to mean five years after registration.

The Council agreed that the MRCP examination should continue to be a test of the candidate's knowledge of general medicine. It was thought that it should not be taken earlier than one year after registration.

Training of Physicians in General Medicine

The Council agreed that it was essential that the required training for general physicians should be as elastic as possible within the general framework already agreed upon. It agreed that the following minima should be expected.

1 Candidates should hold a resident appointment in an approved general hospital for at least one year after registration. During six months of this period the post held should be that of house-physician. The remaining six months should be spent in another junior medical appointment such as house surgeon, house-

physician in a special hospital, or resident in one of the special departments.

2 Candidates should hold a clinical appointment such as that of registrar or chief assistant for at least two years in an approved general hospital. During this time he should be encouraged to undertake research work or to hold some additional appointment such as a demonstratorship in a department of physiology, anatomy, pathology, or biochemistry.

3 Candidates should spend at least one year in research or travel or in some non-clinical subject, such as physiology, anatomy, pathology or biochemistry.

4 No rigid requirements should be laid down for the remaining period of training. A general physician should have some knowledge of the work of special hospitals such as sanatoria, children's hospitals, mental hospitals, etc., and appointments in such hospitals should be recognized. A period of six months spent in general practice might be allowed to count as part of the five years' training.

The Council agreed that there should be no rigid order for holding these appointments and emphasized that the times suggested were minimal and not maximal.

EMERGENCY GUARANTEE FUND

The Council of the British Medical Association has decided that an Emergency Guarantee Fund shall be established. The members of the Council will be the Trustees of the Fund. It will be used at the discretion of the Trustees to further the cause of the medical profession on any major dispute which may occur between the Government and the medical profession or in connection with the proposals for a National Health Service. The Fund will be in two distinct parts: Part A and Part B. The A Fund will be for the purpose of providing the general funds from which the administrative propaganda and allied expenditure will be met. The B Fund will be used for the purposes of the A Fund and in addition within the limits of the Fund, for the compensation of individual practitioners who, because of their adherence to the cause of the profession, suffer exceptional financial hardship. The B.M.A. has guaranteed a sum of £100,000 to Fund A. The Trustees of the National Insurance Defence Trust will consider at their next meeting what their contribution to Fund B shall be.

Every member of the profession is urged to guarantee as substantial an amount as he can afford to Part B of the Fund. Normally this guarantee should be not less than £25, and it is hoped that in many cases it will be much more.

Until the Trustees so decide, the Fund will remain in the form of guarantees. If and when the Trustees deem it expedient, in the light of current events, the amounts so guaranteed, by individuals as well as bodies, will be called in and used at the Trustees' discretion in maintaining the interests and honour of the medical profession. Forms of guarantee will be circulated to the medical profession in the next few weeks.

ROCKEFELLER TRAVELLING FELLOWSHIPS

The Medical Research Council announces the resumption of the pre-war arrangement whereby it was enabled to award medical travelling fellowships generously provided by the Rockefeller Foundation of New York. For the current academic year the Council has awarded fellowships to the following:

Geoffrey Sharman Daves B.M., B.Ch., B.Sc., Department of Pharmacology, Oxford University.

John Louis Henderson M.D. MRCP Ed., first assistant, Department of Child Life and Health, Edinburgh University.

Ronald Staley Illingworth M.D. MRCP, DPH, D.Ch., late officer-in-charge of a Medical Division (fluent-col., R.A.M.C.).

Richard Mayon Mavon White, M.B., Physiological Laboratory, Armoured Fighting Vehicles School, Lulworth.

William Alexander Law, M.D. FRCS, late officer-in-charge of a Surgical Division (fluent-col., R.A.M.C.).

Nicholas Henry Martin, B.M., B.Ch., B.Sc., MRCP, late assistant director of pathology, 21 Army Group and B.A.O.R. (fluent-col., R.A.M.C.).

Robert Lawrence Richards, M.D., assistant physician, Neuro-vascular Unit, E.M.S. Hospital, Gogarburn, Edinburgh. (Drs. Henderson and Illingworth were awarded fellowships in 1939, but were unable to take them up owing to the war.)

Reports of Societies

TUBOCURARINE CHLORIDE IN ANAESTHESIA

What was described as a "milestone in anaesthesia" was discussed at a crowded meeting of the Section of Anaesthetics of the Royal Society of Medicine (about 200 were present) on March 1, with Dr. GEORGE EDWARDS in the chair. Experiences with *d*-tubocurarine chloride were described by two Liverpool workers.

Dr. T. CECIL GRAY said that it was appropriate that in this centenary year of Morton's discovery another new advance, which might prove to be equally significant, should be under discussion. Curare was a poison used by South American savages, between the Amazon and the Orinoco, for smearing on their arrows and darts in hunting and war. The origin of this "flying death," made from certain plants with other deadly ingredients, such as the poison fangs of snakes, was surrounded by esoteric magic and superstition, and very little more was known about it now than when it was discovered in 1812 by Charles Waterton, who described it in his *Wanderings in South America*. In 1935 Harold King gave the name tubocurarine to an alkaloid isolated from crude curare, and later Prof. Mackintosh of Nebraska University prepared an extract of so-called standard potency. The compound *d*-tubocurarine chloride was used in this country from 1934 in the treatment of tetanus, and in 1942 Griffiths at the Homoeopathic Hospital, Montreal, first used the drug as an aid to anaesthesia.

The speaker's colleague, Dr. John Halton, had been using it at Liverpool since November, 1944, but it was not until April, 1945, that its possibilities began to be realized. The crystallized extract, prepared by Burroughs Wellcome, had proved to be of standard potency, but the pharmacology and exact nature of the drug were as mysterious as the preparation of the crude substance. Curare had no action when taken by the mouth; hence the safety of the native who ate his prey. On subcutaneous administration the action appeared within twenty minutes, and on intravenous administration within ten seconds, taking three to four minutes to reach the maximum. Having entered the circulation, it was in part changed by the liver and in part excreted unchanged by the kidneys. In the presence of renal damage of any extent an otherwise safe dose might cause considerable embarrassment. Recent work suggested that the substance prevented the action of acetylcholine, which was produced at the neuromuscular junction, and that this was the mechanism whereby relaxation was brought about. It depressed reflexly the laryngeal and bronchial reflexes, preventing that life of the anaesthetist, spasm. It had been said that it caused contraction of the gut, but experimental evidence in animals showed that the gut was placid and inactive. The present pharmacological opinion was that the liver and kidneys were completely unaffected. The action on the heart and cardiovascular system required a full investigation. So far as the work had gone tubocurarine chloride produced no effect on the electrocardiogram in the doses used clinically. He showed the electrocardiogram of a patient. Two minutes after the injection of 0.5 g. pentothal a slight effect was to be observed on the T-wave, but the subsequent administration of 20 mg. tubocurarine chloride had no further effect or perhaps even brought the T-wave back to normal.

Production of Relaxation

The compound when first received must be sterilized. It was autoclaved at 10 lb. (4.5 kg.) pressure for twenty to thirty minutes. On no account must moisture be allowed to enter during autoclaving. At first he had favoured a very dilute solution, but a concentrated solution, containing 10 mg. to the ml. of distilled water, was now used. The compound was not in itself an anaesthetic. It was used as an adjuvant in order to obtain good relaxation. For a short procedure, such as laryngeal intubation, 15 mg. was injected, with a moderate dose, say 0.5 g., of a quickly acting barbiturate. A dose of 20 mg. was sufficient to relax the average healthy adult abdomen; the very obese might require 24 mg. The effect of this initial dose would persist for a varying time up to forty minutes. There was some cumulative effect, and subsequent doses, if these

were necessary, might be smaller. With old people an initial dose of 10 mg. was suitable.

With this compound a perfectly relaxed abdominal musculature was obtainable in a patient who was still able to respond to painful stimuli by movements of a limb. No untoward side-effects had been observed during administration. In the hands of a competent anaesthetist fully conversant with the trend of modern technique the drug was a safe one, and the results more than justified its use. The surgeon was presented with "perfect blotting-paper relaxation" at any time and quickly. Of his major cases—most of them abdominal—98% had their reflexes fully recovered at the end of the operation. After such operations as gastrectomy and cholecystectomy, patients had been able to carry out breathing exercises within half an hour of return to bed. Post-operative vomiting was lessened in quantity though not markedly in frequency. He believed that there were indications for the use of this drug in every abdominal case and in most thoracic cases. It was of special benefit with poor-risk patients.

Value in Thoracic Surgery

Dr. JOHN HALTON said that his own chief interest was in anaesthesia in relation to thoracic surgery, and it was in the course of his search for a perfect method that he was led to the use of *d*-tubocurarine. In October, 1943, he was using pentothal as the sole agent for the production of anaesthesia for thoracic work, finding the patient's recovery and the post-operative course much smoother. The use of pentothal, however, was accompanied by several disadvantages; cough and laryngeal spasm appeared with annoying frequency and sometimes led to an uncontrollable spill-over of secretion, which meant that the operation had to be postponed for that day. Moreover, each successive fractional dose, while it produced a little longer period of anaesthesia than the one before, did so at the cost of an ever-increasing length of recovery period. Later there came into his possession 100 mg. of tubocurarine chloride, of the pharmacological properties of which he was in complete ignorance, and he waited for what he judged to be clinically a suitable thoracic case. In that first case the operation lasted about one and a half hours, 1.1 g. of pentothal and 25 mg. of tubocurarine chloride were administered, and oxygen was supplied in a closed circuit throughout. He was amazed at the degree of control obtained, and the same procedure was followed in further cases with equally satisfactory results. It was not until the end of March, 1945, that he received regular supplies of the drug. The rapid induction because of the absence of spasm, and the quick recovery and trouble-free convalescence commended it to his surgical colleagues. One interesting fact was that there appeared to be a synergism between the barbiturates and the tubocurarine or between their combination and the inhalation agent. The drug itself was not an anaesthetic, and in smaller doses did not prevent movement. He gave 17.5 mg. to a conscious patient as a therapeutic measure in an attempt to cure a phantom tumour of the upper abdomen, which simulated exactly a pancreatic cyst. Some interesting facts were learned from that case, which was cured. When he gave 15 mg. of the drug and a dose of barbiturate less than that normally required to produce a motionless patient there was no reaction to painful stimuli. If any inhalation anaesthetic was administered to a patient who had already received a barbiturate and the tubocurarine an absolutely minimum amount was all that was necessary to take him to a deep plane, but whether it was correct to regard that as synergistic action the speaker was not prepared to argue.

Three Methods of Use

Dr. Halton proceeded to describe three main ways of using the compound. A mixture of 15 mg. tubocurarine chloride and 0.5 g. pentothal might be injected for such a procedure as oral endoscopy. The respiration after two or three minutes became very shallow, the jaw was completely relaxed, there was no spasm or cough when the airway was inserted, and the patient was able to tolerate straight away without distress an anaesthetic vapour strong enough to maintain the anaesthesia. The induction time was thus greatly shortened.

The next method was the use of tubocurarine chloride with intermittent barbiturate injection. This was their standard method of effecting anaesthesia. After induction small incre-

ments of 0.1 g. of the barbiturate and 2 to 4 mg. of the chloride were added at a time. If the length of the operation were such that too large a dose of the barbiturate might appear to be required the practice was to maintain a minimal amount of cyclopropane and ether. These patients showed surprisingly little alteration in the pulse rate, and even after severe abdominal operations were co-operative on return to the ward.

The third method was the intermittent fractional injection of between 15 and 30 mg. of tubocurarine during the course of ordinary inhalation anaesthesia. This was done to produce the necessary relaxation while still keeping the patient in a light plane. Whatever means was used oxygen must be supplied, preferably in a closed circuit. The drug was very rapidly eliminated. There was no evidence that it had any latent toxicity. The same held good for the barbiturates in the doses employed. Vomiting in thoracic cases was a thing of the past; in abdominal cases the incidence appeared unchanged, but the degree of severity was much lessened.

He and his colleague had given this compound in 1,040 cases. Among these, two deaths which might have been attributed to the anaesthetic had occurred. The post-mortem findings in each case showed gross myocardial damage, and this, coupled with a degree of anoxia, had probably terminated life. In the assessment of post-operative thoracic results there were many difficulties. Changed anaesthetic methods and operating techniques rendered the collection of comparative figures almost useless. With the advent of tubocurarine chloride more extensive surgery had been successfully practised in cases of the poor-risk type. Post-operative complications were very much lessened, and the bodily well-being of the patients after operation was improved beyond anything of which he had had previous experience and must be seen to be believed. This was a powerful drug and a safe drug, but it should never be used by anyone not fully conversant with the care of the apnoeic patient. Further, it should not be used in cases of extensive renal damage.

Surgeon's Testimony

Mr. C. A. WELLS said that much of this work had been done in his own department of surgery. He was sure that many people were alive to-day—patients who had survived operation—who would not have been alive or have had operation at all had it not been for this method as practised at Liverpool during the last eighteen months. The advantage in the theatre was the quick induction, the full degree of relaxation, and the very interesting warning when the anaesthetic had become a little light. There appeared to be a selective action: patients in whom the anaesthesia had become light were able to raise the knee on the table while the abdomen was still fully relaxed. When such a warning was received the anaesthesia could be deepened in a moment. On return to the ward the patients were rapidly co-operative. He had for many years believed that the end-results were facilitated very much by the patient's assistance in breathing, moving, and coughing, and these patients were able to give that assistance.

Dr. FREDERICK PRESCOTT said that in certain experiments with the drug he had found that a dose of 10 mg. intravenously had very little effect; a dose of 20 mg. paralysed the muscles of the arms, legs, and face, but had no great effect on the diaphragm; a dose of 30 mg. produced complete paralysis. This was the maximum which should be given at any one time. Experiments had also been carried out with a form of intramuscular drip, giving 1 mg. a minute; 30 mg. given in that way over half an hour had not very much effect, so that if this compound were used it should be given in a certain maximal dosage and given intravenously.

Dr. F. B. MALLINSON asked whether it was likely that soon the compound would be presented in solution. He also suggested that as this was a new drug it should not be assessed in terms of safety until the cases numbered 10,000. Deaths under chloroform anaesthesia numbered only 1 in 4,000. Dr. HARRIS asked for information about the use of the drug in genito-urinary operations. Dr. G. S. W. ORGANE spoke of the critical nature of the dose. A certain dose might produce very little obvious effect, but a slightly higher dose would produce more than was wanted. Dr. E. S. ROWBOTHAM had had an experience of 90 cases altogether. Some endeavour had been made to assess the dose, in terms of body weight, and the figure of 2.5 mg. per stone (6.2 kg.) had been arrived at for the average case. Most

of the operations were gastrectomies, and the anaesthetic result was satisfactory. Dr. C. L. HEWER mentioned the occurrence of ocular effects. Of 37 cases 19% had complained of blurring of vision lasting from a few hours to three days. The discussion was continued by Dr. A. H. GALLEY, Dr. M. D. NOSWORTHY, Dr. LOFTUS DALE, and Dr. J. W. TREVAN.

Dr. HALTON, in reply, said that the compound had been used in genito-urinary work provided that there was no definite evidence of extensive renal damage. He agreed as to the critical dosage and the narrow margin between under- and over-dose. This was a difficulty, especially in children. A warning was given when relaxation was becoming inadequate—namely, that it became a little more difficult to "aerate" the patient. Dr. GRAY said that no ocular residual symptoms had been observed in his series of cases. His attention had been called in a few cases to retention of urine, but it had always cleared up and was not considered a serious complication. In their abdominal patients they did not inject 30 mg. in a single dose.

Correspondence

Medical War Relief

SIR,—Three months have passed since the second appeal for subscriptions to the Medical War Relief Fund was published in the *Journal*. At that time the balance in the Fund was only £25,000, and it was stated that the sum of £100,000 was likely to be required during the next year.

The committee of the Fund is grateful to those who have responded promptly to the appeal; but they are only a small minority of the profession, and the total of their generous contributions, amounting to some £10,000, falls far short of the "target." As was expected three months ago, the number of applications for assistance has continued, and still continues, to increase. At the present time more money is being paid out than is coming in. The declining balance in the Fund must be greatly reinforced if the committee, in dealing with the many deserving cases which come before it, is to be able to provide really effective help without anxiety as to the claims of future applicants being prejudiced.

The objects of the Fund—the assistance of our professional colleagues who are temporarily in financial straits as a direct result of the war, and of the widows and children of those who gave their lives—cannot fail to command the sympathy of every medical practitioner. Will those who have overlooked the need please give their assistance now, either by responding to any local appeals received from their Panel Committees or B.M.A. Divisions or by sending their cheques (payable to the Medical War Relief Fund) to the honorary treasurer of the Fund at B.M.A. House, Tavistock Square, W.C.1. He gives twice who gives promptly. Generous help is needed, and it is needed now.—I am, etc.,

H. GUY DAIN,
Chairman, Medical War Relief Fund.

Thiouuracil in Hyperthyroidism

SIR,—Since reading your leading article on "Thiouuracil in Hyperthyroidism" (Dec. 18, 1943, p. 783) I have been working on this problem with my associates Drs. Tarrida and Castello. We believed, and we soon confirmed, that the theories put forward by the MacKenzies and E. B. Astwood are not sufficient to explain all the phenomena occurring in connexion with the use of thio-compounds. In our experience there does not elapse any so-called "delay or latent period," as contended by them, before the drug acts positively on the patient. Though it is true that in clinical experience some time does elapse, this does not mean that from a physio-pathological standpoint the drug fails to act right away. Since we have been able to show that the drug acts immediately, and modifies the vegetative rates, especially the basal metabolic rate, we consider it no longer logical to explain its action as pending histochemical changes in the thyroid gland, and a subsequent drop of the blood thyroxine level. The drug begins to work before all this can possibly take place, and the "latent or delay period" does not exist. This can be demonstrated quite simply. Measure the basal metabolic rate of anybody, then administer a small

dose of any thio-compound whatever, and measure again the basal metabolic rate half an hour later if the dose was given orally, or a few minutes later if it was injected. In most cases a metabolic drop is observed, the extent of which varies considerably but is generally significant. If the basal metabolic rate determination is repeated often enough, a graph can be made of the corresponding figures, in a way similar to that of glucose tests (this is by no means a hint that there exists any connexion between them, although it might be argued that in both cases we seem to deal with a biological system of agonists and antagonists). In a small number of cases an inverted, or reverse, effect is noted—i.e., a rise in the basal metabolic rate over and above the initial level. This is exceptional, yet we feel that this phenomenon, together with the rapid response, may suggest the intervention of some vegetative link.

Generally speaking, the hyperthyroid's metabolism drops most, that of normal people drops less, and the hypothyroid's least of all. Patients with neuro-vegetative instability show the most marked variations; this is to be expected.

When we observed that small doses—even smaller than those commonly used in daily treatment—were sufficient to determine ample drops in the basal metabolic rate, we deemed it worth while trying these new drugs in small doses in the treatment of our hyperthyroid patients. Results were satisfactory in a series of 23 such patients, who received total daily doses of 0.25 to 0.60 g. thiourea, or 0.07 to 0.15 g. methylthiouracil in fractionated quantities. No disturbances of the digestive tract, no hypersensitivity, and no toxic troubles were observed, and the results were as satisfactory as those with far larger doses usually employed elsewhere. Permanent stabilization of basal metabolic rates at normal figures was obtained usually after four to six weeks' treatment. Patients felt better from the end of the first week or even before. None of them showed hypothyroidism.

An alteration of carbohydrate metabolism of apparent diabetic type was favourably controlled in one case, the glycaemic type of curve being brought back to normal. Two cases showed complete arrhythmia: in one of them normal rhythm was restored, whereas the other one, which had lasted for years, could not be controlled. In no case did the goitre increase; on the contrary, it became smaller, or even totally disappeared. This is, in our opinion, one of our most noteworthy observations, together with the absolute lack of digestive troubles, of the type referred to by our colleagues on applying the usual doses of thiourea, and which affected, according to their statement, up to 25 to 33% of their cases.

Whilst, according to the MacKenzies and Astwood, the drug interferes with the thyroid hormone production in the thyroid and, it may be that it also immediately interferes with the action of thyroxine on tissues, which would explain the rapid response. Only further research will clear up this most interesting point.

The demonstration of the immediate action of the drug was based on observations carried out on more than 100 patients, among whom there were cases of hyperthyroidism, endocrine disturbances of other types, cases of general illness, and also healthy people. The number of basal metabolic rate determinations done is over 500. These results were addressed on two different occasions to the *Asociación de Endocrinología y Nutrición* at the Academy of Medical Sciences, in the first instance on June 11, 1945, under the title "Revisión de las teorías actuales sobre el mecanismo de actuación de los sulfoconjugados a la luz de experiencias propias." They were confirmed in the *Instituto de Investigaciones Médicas* at the School of Medicine, and in the Institute of Pharmacology, and various colleagues have also checked personally, in their private experience, the rapid action of thio-compounds.—I am, etc.,

Faculty of Medicine, Barcelona.

CHRISTIAN DE NOGALES.

Treatment of Amoebiasis

SIR,—I imagine that more authoritative voices than mine will have been raised in protest against the astonishingly ill-informed letter of Dr. E. Snell (Jan. 12, p. 68) on the subject of the treatment of amoebic dysentery.

In the face of all current medical opinion he states that a course of 10 gr. (0.65 g.) of emetine should be given. It cannot be too often emphasized that for the dysenteric types

of amoebiasis two, or at most three, injections of emetine are sufficient. If Dr. Snell had ever gone so far as to check up on the progress of dysenteric patients with the sigmoidoscope he would have realized the great speed with which the ulceration is healed by emetine injections. To inflict an extra unnecessary week of injections of this dangerous drug is a gross imposition on patients. If he still insists on giving a long course of emetine (which, indeed, is necessary only in amoeboma or in chronic infections of liver or lung) dare we hope that he keeps his patients in bed for at least a further week after the injections have ceased, and that he scales the dosage of emetine down for lightweight patients? Dr. Snell apparently rejects entirely the recent improvements represented by the introduction of diodoquin and penicillin.

Finally, may one suggest to Dr. Snell the use of the sigmoidoscope as a diagnostic measure as well as a test of cure, and point out that if he looks only for ulcers (as his letter suggests) he will be missing at least 80% of infections.—I am, etc.,

C. F. J. CROPPER,
Major, I.A.M.C.

Rawalpindi.

Cardiac Beriberi

SIR,—When I was a student I recollect being told that the surest way to get propelled from an examination room by *vis a tergo* was to make a diagnosis of beriberi. Time has brought us round in a full cycle, and now, judging from recent articles, it must be essential to make that diagnosis in order to stay in the room.

It appears that if any patient with heart disease is put to bed and given large doses of thiamine he will quietly get better or quietly die. In the first instance this is diagnostic of beriberi and in the second diagnostic of resistant beriberi. Here is a great advance in cardiology. Neurology has also progressed, for it is now known that any neuritic pain if treated with very large doses of thiamine for a long time will disappear or persist. Obviously, therefore, it must be due to a B₁ deficiency of either the curable or incurable type, and I see the followers of Withering and Bright are making similar profound discoveries in regard to dropsy.

These remarks are called for by a recent article in the *Journal* (Feb. 23, p. 273) in which an x-ray photograph is shown of an enlarged heart in an anaemic girl which has no resemblance to the heart in beriberi, and yet was diagnosed as such because the patient recovered in spite of injections of thiamine. Drowned in the depths of a meaningless past is the memory of those stout little girls—housemaids, wardmaids, and probationer nurses—with chlorosis who continued their hard work until finally, pale, tired, and with dilated hearts, they came to see the doctor because their output of work was falling.

In true cardiac beriberi the response to an adequate injection of thiamine is one of the most dramatic reactions seen in medicine, the patient usually feeling the effect in a few minutes, while it is objectively demonstrable in a couple of hours and obvious to the most casual observer in a day. Therefore in thiamine we have a most valuable aid to diagnosis, for if no result is seen in a day then the diagnosis of cardiac beriberi is either wrong or incomplete: frequently incomplete, for beriberi can complicate any heart lesion as well as the dilatation so common in anaemia, whatever the cause. This dilatation in those doing hard physical work seemed to cause my students more difficulty in their differential diagnosis than any other cardiac disorders, but any doubt can be quickly resolved by a therapeutic test.—I am, etc.,

London, S.W.1.

R. BRUNEL HAWES.

Effect of Blast on the Ear

SIR,—The letter of Lieut.-Col. J. F. Birrell (Feb. 23, p. 292) calls for further comment. His communication brings up three points: the lack of equipment of the British Army otologist, the impracticability of reviewing soldiers exposed to blast effects, and the impossibility of examining men under 40 years of age prior to their discharge from the Army.

I knew that my British colleagues were handicapped in the accurate assessment of their hearing tests in the two theatres of war in which I served—the Middle East and the Central Mediterranean Commands—but I am astounded to learn that such a state exists in the United Kingdom.

where one would expect to find facilities for full investigations. It would appear that a systematic study of blast deafness has not been attempted by a research unit of the R.A.M.C., apart from the efforts of individual otologists, who, however can do little by themselves while on active service. This contrasts unfavourably with the useful otological research which has been conducted with energy by the E.N.T. staff of the Central Medical Establishment of the Royal Air Force. Surely our electrical engineers, who have done so much in other fields, would be able to construct, and calibrate, a suitable audiometer, obviating the necessity for importing these instruments from the U.S.A.? In a recent discussion at the Royal Society of Medicine Mr Daggitt mentioned that an instrument had been made for him by R.E.M.E. from disused radio parts. Not only is such a procedure practical, but the cost of construction should not be prohibitive.

Under present conditions I agree that it would not be possible for otologists on active service, and in this country, to carry out the investigations suggested in the two groups of men, but this negative attitude is no excuse for a failure to do so should the necessity arise at a future date. A reorganization of the otological services would be called for, necessitating adequate equipment and staff. In my opinion it is not necessary to have an otologist as the audiometrician. I myself trained two orderlies—highly intelligent young men—in the use of this instrument, and when I was satisfied with their proficiency they carried out these investigations, referring any difficult cases, such as those with possible psychological exaggeration, to me. This saved an enormous amount of time. It should not be impossible to find other suitable men to train for this work. A view which I hold strongly is the need for the establishment of a school of audiometry, with the power to issue a certificate of proficiency in this part of our work. These trained audiometricians would be of invaluable assistance to the busy otologist in civilian as well as in wartime practice. On the clinical side, an excellent opportunity for becoming familiar with normal and abnormal otoscopic appearances would be afforded to young doctors who would be attached to the E.N.T. specialist as E.N.T. "trainees." Any difficulties encountered would be referred to the trained specialist. Such a scheme should not be difficult or impracticable to organize in time of war.

As a matter of personal opinion, I feel that men with traumatic deafness should not be returned to the line, and I consider that it is the duty of the otologist to protect his patient from possible preventable deafness. When this was explained in a straightforward way to my patients I had no difficulty in convincing these men that it was in their best interests that they be graded for base duties only, despite their desire to return to their old units. We all know the old adage, "Prevention is better than cure." How much better is it, then, when there is no cure as in the case of some patients with high-grade nerve deafness?

In conclusion, I submit, Sir, that it is not impracticable to carry out the procedures I have suggested in the future—I am etc.,

E.N.T. Specialist 2 N Z E F

Loss of Vision following Haemorrhage

SIR,—None of your correspondents has stressed the fact that in order to produce this condition it is almost essential for the haemorrhage to be a recurrent one. Hence the reason why, although thousands of all ages were bled white, so few cases have been recorded in the two great wars.

In the old days repeated blood letting was a well known cause of this type of blindness, and Moliere, with his usual cynicism towards the medical profession, tells the story of a young man who, for some trifling malaise, was bled time and again. Eventually the young man complained that his sight was getting misty. The "fool doctor," however persisted repeated the performance and the young man went quite blind.

Another point of interest is that the patient may say that the black out (like the curtain of the ancient Roman theatre) came from below upwards. In after-years eliciting this history may, in a case of obscure optic atrophy, be of diagnostic importance—I am, etc.,

London W 1

EUGENE WOLFF.

Third-generation Syphilis

SIR,—I note in the *Journal* of Oct. 27, 1945 (p. 585), which has just reached me, that Dr. C. C. Wedderburn points out that the case of third generation syphilis I reported in the *Journal* of Aug. 11 is lacking in conclusive evidence. That the mother herself is a congenital syphilitic can be concluded from the fact that she denies any extramarital intercourse, and I think one must accept her word for that. Should this, however, not be acceptable as evidence one must consider the time of possible infection. The elder daughter shows no signs of congenital syphilis, so it is reasonable to assume that it was after her birth. If this were so, and we accept the mother's statement that she has not had any antisyphilitic treatment, would not one expect to find some signs of congenital syphilis in the youngest child, who, in fact, shows no signs?

Dr. Wedderburn also mentions the fact that the mother's present age was not included in the report. I cannot see that this is relevant, but it is 40—I am etc.,

Singapore

C. J. V. HELLIWELL,
Surg. Lt.-Col., R.N.V.R.

Acute Pancreatitis

SIR—I was much interested in Mr. Norman Godfrey's article on acute pancreatitis (Feb. 9, p. 203). This condition is associated with a very high mortality (50%), and is notorious for the fact that in most cases the abdomen is opened for some other condition. Surgical treatment usually consists of a laparotomy with drainage of the abdominal cavity or lesser sac and with or without cholecystectomy. The following case, I think, be of interest as the result suggests that a more conservative method of treatment might be associated with an appreciable lowering of the mortality rate.

A married woman aged 34, a Gibraltarian refugee, was admitted to the E.M.S. Hospital, Barking, at 1.20 p.m. on Feb. 19, 1941, complaining of severe abdominal pain which had started 7 days previously but had considerably worsened during the two days prior to admission. The pain was of a spasmodic nature and situated chiefly in the upper abdomen, although sometimes referred to the interscapular region. She had had no bowel action for a week and had vomited several times in the previous three days. Two enemata were given, without result, in the two days before admission. There was nothing relevant in the medical history except a few mild attacks of colicky epigastric pain during the previous two years, following an attack of jaundice at Gibraltar.

Examination on admission showed a very obese, nervous woman, slightly cyanotic and dehydrated with a dry, furred tongue, central distension of the abdomen with visible peristalsis, marked tenderness in epigastrium, right hypochondrium, and right iliac fossa. There was guarding of both recti but no rigidity. BP 155/70, T 100°, P 100, R 24. Enemata were given without result and diagnosis of intestinal obstruction due to gall-stones was made, the cyanosis being attributed to respiratory difficulty resulting from the marked abdominal distension and general obese condition of the patient.

Morphine 1/6 gr (11 mg.) was given and gastric lavage with a Ryle's tube started immediately, while an intravenous glucose saline drip was set up. An exploratory laparotomy was carried out through a right paramedian incision at 8 p.m. on Feb. 19 under gas, oxygen, and ether anaesthesia. The presence of fatty necrosis and blood stained fluid in the peritoneal cavity left no doubt as to the diagnosis of acute pancreatitis, which was further confirmed by the gush of blood stained fluid that escaped when a finger was passed through the foramen of Winslow into the lesser sac. The pancreas was felt to be hard and swollen, while the gall bladder was pale, distended and contained stones. Some fluid was removed from the abdomen by a sucker, but as the patient was now practically moribund the abdomen was rapidly closed without drainage. The whole procedure took about 15 minutes and the patient, after being given an injection of 1 ml. of nile hamide was returned to the ward. A grave prognosis was given to the patient's relatives. As a somewhat forlorn hope soluble protosil was added to the intravenous glucose-saline solution which she was receiving and by 10 a.m. the following morning Feb. 20, she had had 10 ampoules of pronal and her general condition was greatly improved. Being now able to take fluids she was put on a course of sulphapyridine, and 26 hours after the operation to everyone's surprise, she was looking very much better and beginning to take notice, after which, except for a slight daily rise of temperature until the fifth day, she made an uneventful recovery, getting up on March 10 and being discharged on March 21. She had altogether 23 g. of sulphapyridine. The diastolic index of urine on Feb. 20 was 500 units.

Six months later cholecystectomy was performed and a number of stones of mixed type removed. No trace of the preceding pancreatitis was seen during this operation and the pancreas felt quite normal. This case was followed up, and when the patient was last seen, on June 9, 1943, she was perfectly fit and gaining weight.

It seems to me that the recovery in this severe case of acute pancreatitis cannot unreasonably be ascribed to sulphonamide therapy, as the operation consisted merely of opening and closing the abdomen, without drainage and without removing much of the fluid contents. This case strongly supports the infective theory of the causation of acute pancreatitis, and it is tempting to suggest that in future the use of penicillin in this condition may have a considerable effect in reducing its high mortality.—I am, etc.,

Ronkswood Hospital, Worcester.

HIREN DE.

Overdose of Ephedrine

SIR,—I think the following case may be of interest, and perhaps some of your readers may be able to give me some information on the subject.

A woman patient of mine of long standing took a large amount of ephedrine suicidally. She was a chronic asthmatic, and fortunately had nothing more toxic to hand. She had been through an emotional disturbance and took this hoping that it would stop her heart. I cannot be sure how much she took. She thinks it was "about 40" 1/2-grain (32-mg.) tablets. In my experience the numbers taken are apt to be exaggerated, but it is certain that she took much more than the proper single dose. I saw her an hour afterwards, and she was comfortable, complained of nothing but nausea (she had had mustard and water and black coffee), and she had no urgent symptoms. Her pulse was 108, of fairly good volume, respirations normal, colour normal, and the only obvious abnormality was dilatation and fixation of both pupils. I could find no record of poisoning by adrenaline or ephedrine. My edition of *Martindale* says of ephedrine hydrochloride: "1 gr. [65 mg.] has been known to produce toxic phenomena"; while of ephedrine sulphate it says: "Maximum daily dose said to be 4½ gr. [292 mg.]." This patient thinks she must have taken about 20 gr. (1.3 g.). She must have taken much more than 4½ gr. anyhow.

I stayed in the house from 10.35 a.m. till 2 p.m., during which time she vomited twice, bringing up a quantity of coffee-coloured fluid. As there were no urgent symptoms I adopted an expectant attitude. I did not wash out the stomach, and when I left she was comfortable, and the only abnormality was the dilated pupils not reacting to light or accommodation, though she said she could see normally, and she was able to count fingers correctly. I met her husband next day, and he said she was completely recovered.

It would be interesting to know if there are any other records of overdosage with ephedrine, and if so what effects were observed and what antidotes should be used. I presume that gastric lavage and vasodilators would be indicated. But I was anxious to avoid a stomach tube in this case, if possible, from knowledge of the patient, and it actually proved to be unnecessary. While no urgent symptoms of any kind occurred, one might, I suppose, expect marked cardiac depression following over-stimulation, but this does not seem to have happened.—I am, etc.,

Nanyuki, Kenya Colony

G. DUNDERDALE.

Overdose of Pethidine

SIR,—This description of what would appear to be a case of pethidine overdose may be of interest.

A male patient, employed as a company secretary, aged 53 years, who suffered from regional ileitis was told to take two tablets of pethidine every four hours for its relief. On Dec. 28, 1945, he took a first dose, and by Jan. 1, 1946, he had taken a total of 36 tablets. On that evening he had what he described as a "brutal" headache and went to bed, his only other complaint being that he felt sweaty. His temperature was normal and he slept well. On Jan. 2 he still had a headache, but he went to work. I saw him at 11 a.m., complaining of headache and feeling sweaty. His temperature and pulse rate were normal, and a blood slide was negative for malaria parasites.

He drove home to luncheon as usual, and had actually started his meal when he was overcome with a prickly sensation all over his body, head, and limbs. He went into the next room, and a minute or two later he had an attack of amblyopia, which lasted a minute or two. His wife, who was with him, saw him go "very white and then very purple." On recovering his sight he went to lie down. He had a sensation of "pins and needles" across his chest and in his feet and hands. I saw him half an hour later and found him

a brilliant boiled lobster colour all over. He complained of irritation in the parts previously affected with "pins and needles." His temperature and pulse rate were normal. He showed rapid improvement after the subcutaneous injection of 1 in 1,000 adrenaline 10 ml (0.6 ml.). Three hours later he was quite normal.

—I am, etc.,

Nairobi

J. R. GREGORY.

Non-absorption of Mepacrine

SIR,—I have seen tablets of atebirin passed apparently unchanged in the stools. The patient was a Tamil woman and admittedly had slight diarrhoea, but it would be interesting to know whether the frequency of such an occurrence has been investigated, and whether it might have been the cause of non-absorption of mepacrine in Dr. John Yudkin's case (Feb. 23, p. 271). It has been my custom to prescribe mepacrine tablets crushed.—I am, etc.,

Tunbridge Wells.

J. G. REED.

Homosexuality

SIR,—Like many of your correspondents, I was moved to something like indignation over the case in which the repetition of a moral offence led to a sentence of fourteen years' penal servitude. A simple reaction would be to say that our law is out of date and that the sentence is comparable with the old custom of confining a lunatic with chains. Yet, we may ask, is not medicine also a little out of date, and are we not in addition rather led by prejudice in our attitude to sexual aberration?

All will agree that the public must be protected, and many will feel that the offender, too, ought to be guarded against his own abnormality. Sometimes a psychiatrist may perhaps achieve a permanent cure of homosexuality provided that the patient himself is willing to co-operate with sufficient determination. But there will be a residue of these subjects for whom psychology is not a therapeutic foundation on which we can securely rest. Besides such aetiological factors as an unfortunate early environment or chance coincidences in the past, we have to consider the hormones on which our sexual psychology is largely based. A research into this matter is surely desirable. Meanwhile the worst case possible can be easily cured by castration. In this way we can certainly protect both the public and the patient, at the same time inflicting on the latter a minimum of hardship. This admirable remedy is at present disregarded merely because both medicine and law remain ignorant and prejudiced against its advantages when put to a proper therapeutic use.—I am, etc.,

Marlborough.

HAROLD BURROWS.

SIR,—One can agree with your correspondents that imprisonment, for first offenders at any rate, is not helpful treatment for the homosexual or his victim. The latter's interests and those of the public are best served by a cure of the homosexual, if this is possible.

I think your correspondents forget the severity of the law in dealing with other habitual offenders against society. The burglar or housebreaker who is caught loitering on or near enclosed premises with intent—that is, with a jemmy or other tools of the burglar's trade in his possession—is severely dealt with by the stipendiary, though no crime has been committed.

Do other experts agree with the opinion of Dr. E. A. Bennet, expressed in his letter (Feb. 23, p. 289), that the homosexual's victim suffers little from his experience? This is hard to believe, but comforting if true.

Is the severity of the law and its officers in these cases not due to an old but dying tradition—the necessity for stamping out rigorously all abnormal sexual practices which prevent the true function of sex—i.e., the procreation of the race? History shows terrible examples of the fate of peoples who blinded themselves to this truth. Agreed that it is an anachronism that it should survive in the criminal court, in these days of widespread sexual promiscuity in the youth of both sexes, easy divorce by the law, etc.

In the particular example quoted in recent letters a scout-master was prosecuted. He had had two previous convictions for homosexual crimes. Surely some discretion and common sense should be used in the appointment of officers in control

of youth organizations of both sexes. The very acceptance by this individual of a position as scoutmaster puts him on the same plane as the burglar "with intent." He knew that his position of trust, honour, and responsibility gave him scope for his vice—for ugly vice it is to me, and many others, whatever the view of experts.—I am, etc.,

Batley Works

JOHN J. FITZPATRICK.

SIR.—The writers of the letters on homosexuality exhibit the same type of mental process as those who sign reprieve petitions for murderers—i.e., infinite pity for the criminal, and little, if any, for the victim. It is pertinent to inquire if Dr. E. A. Bennet has any sons of his own, and if they had been "unfortunate enough to have been on terms of sexual intimacy with a homosexual man" would he show the same complacency that he does with regard to other people's children? How does Dr. Bennet know that the victims of homosexual practice suffer no psychological trauma? The revolting statement that "there are other factors in such relationships, and that sexual activity may play a minor part in a friendship which often has in it much of value," is just obscene balderdash.

The British public has cause for gratitude that buggers—I prefer the Biblical name—frequently receive the sentence they deserve at the hands of a judiciary that places importance on the protection of young people's morals, and it is comforting to know that the boys of Edinburgh are safe for fourteen years from the salacious attacks of at least one of these perverts. The late Sir Horace Avory is reported to have said that it would be a bad day for this country when the administration of justice is handed over to gentlemen from Harley Street. His Lordship must have been a student of the correspondence columns of the *B.M.J.*—I am, etc.,

Leamington Spa

W. LUNLEY.

Homosexuality and the Law

SIR.—The medico-legal aspect of homosexuality is once more arousing medical interest, and surely it is high time that some modification of the existing law was made in respect of homosexual offenders. Much has been written on the subject, but unfortunately its value tends to be lessened by the divergence of views expressed as to its causation and, more important, its treatment. These views are determined not only by the facts but by the bias of the observer. No considered opinion can surely be given on the question of punishment for homosexual offences until there is more clarification of the two important aspects of aetiology and treatment.

Regarding aetiology, certain general observations may be made. As in other forms of instability, there are constitutional and environmental factors, the weighting of which is often difficult to arrive at as they tend to be interdependent, early environmental difficulties so often being due to instability in the parents. However this may be, there is always some disturbance of the normal child-parent relationship, with, in the case of males, an over-attachment to the mother. This has been interpreted in various ways, such as the Oedipus complex of Freud; but, whatever its interpretation, it is almost always present. Indeed, Magnus Hirschfeld, who admits no particular psychiatric allegiance and who has probably had greater experience of homosexuals than any other authority, states that he has not seen a case of male homosexuality where there was not this emotional overdependence on the mother. A corresponding estrangement in the father relationship is nearly always present—the harsh, cruel, disinterested, emotionally inhibited, or drunken father frequently figuring in case histories. These clinical facts, whatever their interpretation, are easily verifiable by anyone who has taken case histories of male homosexuals. There are frequently other indications of instability in the homosexual—either he tends to break society or society tends to break him, resulting respectively in psychopathy or in neurosis. In the latter case the homosexual urge tends to remain repressed and therefore unrecognized, and the neurosis is the result of an underlying emotional conflict. Although complete emotional development leads to heterosexuality, this is an ideal which is probably achieved less often than is popularly supposed, and unrecognized and therefore inadequately dealt-with homosexual tendencies are present in many people. They may result, for instance, in impotence,

alcoholism, Don Juanism, and may even determine the choice of occupation.

Seeing that homosexuality may be constitutionally and environmentally determined, what is the position when the question of punishment arises? It may be held that, as a heterosexual is liable to punishment if he fails to control his sexual urges, so, too, should be the homosexual. There is, however, this important difference: that, whereas the normal person has some outlet for his sexual impulses, these are not available to the homosexual. No doubt the public interest demands some form of deterrent, but, in considering this, due attention should be paid to causation and the possibility of treatment. Psychiatric opinion differs as to the efficacy of the latter, and certain it is that, unless treatment is genuinely sought—and often it is not—it is likely to be a waste of time on the part of all concerned. Even in those seeking treatment it is unlikely that anything short of a time-consuming reductive analysis will be effective. Probably the best solution would be a period of preventive detention in a special institution for sexual inverts. Here could be concentrated such specialized treatment as is available, and some of the newer and more progressive methods involving groups could be tried out. At any rate, such an institution would provide material for intensive research, and from this it is hoped a better solution of this social problem might emerge.—I am, etc.,

Stamley

B. C. GILSEN.

Homosexuality or Sodomy

SIR.—I was called by the prosecution at the Dorchester Assizes in the early years of this century for a case of this foul disease. The case came under a new indictment following the Oscar Wilde case. The utmost penalty involved was two years' hard labour. Actually the man received a sentence of three months. Why has this indictment been altered? Incidentally the charge was for "the dreadful crime of buggery." According to the teaching of the late Sir Thomas Stevenson the indictment was wrong—it should have been "sodomy" as applied man to man, "buggery" man to beast. To my mind "sodomy" (a good old English word) is far preferable to "homosexuality." Reference to Taylor's *Medical Jurisprudence* will find the meticulous care of the distinction of the above two words.—I am, etc.,

Bournemouth

C. EDWARDS.

Physical Therapy in Mental Disorder

SIR.—There is much good sense in Dr. T. H. B. Gladstone's letter (Feb. 2, p. 179), but his wisdom is vitiated by so many illogical conclusions that his contribution can serve only to increase still further the difficulty of arriving at a balanced judgment on this complex question.

Let us at once concede many of Dr. Gladstone's points. Electro-convulsive therapy and prefrontal leucotomy are relatively new methods, frankly empirical, with after-effects which are not yet completely known; already they have been applied injudiciously by a certain number of under-experienced or over-enthusiastic practitioners. The same can now be said of much gastric surgery in the 'twenties, and of the more recent indiscriminate use of the sulphonamides. (Incidentally, which of these tragedies has been relatively the more frequent: fatal agranulocytosis through the injudicious use of the sulphonamides, or the crippling of potentially creative genius through misguided leucotomy?) On the credit side it is indisputable that a large number of chronic mental hospital patients have by now been relieved of horrible and hopeless distress and restored to some measure of social efficiency through the use of these particular methods, empirical as they may be.

What alternative does Dr. Gladstone advocate? He admits that full use is not being made of psychological methods in most mental hospitals, and himself supplies the reason. It is not due to negligence or ignorance on the part of the medical staffs; the total number of available psychotherapists, of whatever degree of competence or energy, is quite inadequate to deal with the volume of patients who need help of some sort, even if we allow that a purely psychological technique is useful, or even applicable, in all these cases. The assumption would by no means be conceded by all experienced psychologists (vide Dr. H. Crichton-Miller, Jan. 19, p. 103). While awaiting the

desired recruits to their ranks are the existing psychiatrists to do their rounds, as Dr. Frank (p. 104) says, "in an awestruck trance," animated only by the tenuous hope of detecting an occasional Tolstoy or Picasso emerging from his chrysalis of obstinate melancholia or paranoid schizophrenia? Or are they to devote their time to the intensive psychotherapy of 10% of their patients and ignore the 90% remaining under their care?

The methods of E.C.T. and prefrontal leucotomy cannot be dropped out of hand at the bidding of prejudice. Their legitimate sphere can be delimited only on the results of conscientious trial and careful observation by the numerous skilled clinicians who are now doing their best to evaluate them. Included among these observers are many reputable surgeons, as well as clinical psychiatrists of proved reliability.

For this reason I shall welcome the publication of Dr. Frank's 230 leucotomy results, and shall be surprised indeed if his series reveals even one possibility of a creative genius having had his frontal lobes mutilated during a "short mental illness." An ill wind has swept Europe of late years, but British psychiatrists may well feel that good has come to us from the presence of Dr. Jan Frank as an active worker in our ranks. Those who know of his past training and personal philosophy rest satisfied that his clinical judgment is informed by long experience, deep study, and broad humanity, and I am confident that at all events none of his patients has been subjected to ill-considered or excessive use of the electric switch or the leucotome.

"Far too often the mental hospital doctor is below the level of many of his patients in general culture and intelligence" is an opinion frequently expressed by the patients, but, coming from Dr. Gladstone, the assertion seems so extravagant that one feels it could do no mischief did not one know the present tendency of the popular press.—I am, etc.,

London, S.W.1.

H. N. BRADBROOKE.

SIR,—As a very junior A.M.O., a mere doorkeeper in the house of the Spanish Inquisition, it would be presumptuous, even were it not futile, to quote the literature refuting Dr. Learoyd's moving appeal (Feb. 16, p. 251) for liberty of the individual. I have seen agitated melancholics and depressives suffering indescribable mental agony and begging for death transformed in a few days into happy human beings, when formerly their suffering lasted for months, as shown by their old case notes. Against this it is hard to balance hours, even of "fear and dread."

With chronic schizophrenics, still unfortunately as incurable the majority of medical complaints, the problem is admittedly clear. True some are enabled to go home for occasional visits several days, but is this justification for forcibly transforming them from crouching impulsive beings, liable to smash all the windows or their fellow-patients, and coming on the scene can one with a clear conscience forcibly stitch up their gaping wounds? To drug them would be unthinkable, and, alas, one is no longer permitted to chain them to the walls. In locking them up at all grave fundamental issues are raised. I appeal to Dr. Learoyd for further guidance on these delicate and perplexing matters.—I am, etc.,

Netherne Hospital, Coulsdon

J. A. SINDELL.

"Leucotomy"

SIR,—I think there must be many readers of the *Journal* who, like myself, would be very interested to have a clear description of this new operation styled "leucotomy," and a full explanation of its purpose and an account of its after-effects. I have attempted to get some information from medical colleagues, but find they can tell me very little.

In Dr. Reitman's article (Feb. 16, p. 235) one section presents several words of which I confess to being quite ignorant; but I have a comforting feeling that there are many others in a like predicament. Thus we have "dysmetria," "astereognosis," "apraxia," and "perseveration." None of these is to be found in the *Concise Oxford Dictionary*. "Ataxia" is to be found, but not "apraxia." One can guess fairly well at "perseveration," but would think a simple and plainer word, to be found

in any dictionary, might have sufficed. "Negativist" is a dictionary word; not so "negativistic." "Hallucinated" is, to me at least, an awkward-sounding word, but we have to admit that the dictionary does allow the verb "hallucinate." Presumably all the other words have been coined for use in the new science or art of psychiatry, which seems to be acquiring almost an esoteric quality. If so, then let us have a special dictionary to which we may turn for information. But strangest of all is the word "leucotomy" itself. Most "tomies" are self-explanatory, such as "gastrotony," "nephrotomy," etc., but "cutting the white" is anything but self-explanatory. "White what?" one naturally asks.

It seems a severe operation to attempt on purely empirical grounds. As to possible after-effects, one is struck by the shortness of the time that often elapses between the operation and the discharge of the patient. Surely all these cases need the most careful "follow-up" for years.—I am, etc.,

Tunbridge Wells.

E. WEATHERHEAD.

*A *Dictionary of Psychology*, edited by Howard C. Warren, of Princeton University, was published in this country in 1935 by George Allen and Unwin, Ltd. It contains some, but not all, of the words noted by Dr. Weatherhead. "Leucotomy" had not then been coined. This is defined in *Dorland's Medical Dictionary* as the operation of cutting the white matter in the oval centre of the frontal lobe of the brain.—ED., B.M.J.

Effect on Troops of the "V" Weapon Bombardment of Antwerp

SIR,—By a curious coincidence, the first patient I saw after reading Capt. A. G. Freeman's "Effect on Troops of the 'V' Weapon Bombardment of Antwerp" (Jan. 12, p. 58) presented a similar picture to that described. In response to my semi-facetious query, "Have you ever been to Antwerp?" I was somewhat taken aback at receiving an affirmative (as well as gratified by his obvious respect for my clinical acumen). Capt. Freeman may be interested to hear the later history of this case, eight months after removal of the exciting cause.

The patient is an N.C.O. in the R.A.S.C., aged 23 years, with 3½ years' service, who had landed in France in June, 1944, and had been well up in forward areas, with only occasional rests, until cessation of hostilities. He has been in West Africa for three months.

He is now complaining of a feeling of "flatness," and is slack and listless during the day and excessively tired in the evenings. He is nervous and "jumpy," is particularly affected by sudden noises, and sleeps badly, tending to wake and remain awake in the small hours of the morning. As an example, he mentioned that on one occasion he had retired early and was asleep when his room-mate entered, slamming the door noisily. He awoke in an acute state of fear and was unable to get to sleep again that night. He suffers from frontal headaches, boring through to back of head, and not substantially relieved by large doses of aspirin. The tremor of his hands is such that he avoids lighting a cigarette in public for fear of being "ragged." He spoke jerkily, with marked twitching of the face and tremor of head and neck, and kept his hands hidden behind his back, but seemed considerably relieved to be telling his story.

His symptoms had first arisen in August, 1944, but cleared until January, 1945, at which time he was in the Antwerp area. He had reported sick and been given some medicine, after which he had improved considerably. Since then he had had recurrences lasting as a rule some three to four weeks. Surprisingly, he had had such a recurrence while on leave in England after cessation of hostilities. At this first interview he was reassured strongly and given a bromide mixture. As he was working in an office within a very noisy workshop, by arrangement with his C.O. he was transferred to more suitable employment. One week later he was much improved and stated that he was sleeping better. When last seen a week after this he felt so much better as to express the opinion that further medicine was unnecessary.

It was interesting to note his rapid response to sympathy, explanation, and improvement of working conditions, but it still remains to be seen whether his symptoms will again recur.—I am, etc.,

Accra, Gold Coast.

B. STONE.
Capt. R.A.M.C.

Lay versus Medical Administration

SIR.—Sir Frederick Menzies's letter (Feb 16, p 251) will be welcomed and endorsed by every experienced medical officer of health. The national health scheme should provide this country with the best health service in the world if it is wisely conceived and efficiently administered. There is no question that the doctors can give competent attention to the sick at home or in hospital if their efforts are not frustrated and obstructed. There are sound reasons as Sir Frederick shows, why the chief administrative officers of the regional organizations should be medical men, and there can be no excuse for filling these appointments by lay officers, and particularly by lawyers. That medical men are competent administrators was proved by the success of the Ministry's E.M.S. Hospital Scheme, which was managed by medical men in co-operation with a few civil servants. Endless trouble and friction will ensue if the chief administrative officer is chosen because he is a member of the legal profession. The training for that profession is the one least calculated to make a good business manager or administrator, and it is amazing that local authorities, which nowadays are among the biggest businesses in the country, have failed to realize this, or when they know it have been unable to get out of the rut. When a public legal service is imposed on us, will it be suggested that the chief administrative officers should be medical men?—I am, etc.

REPORT 117

J. FAIRLEY

Motive in Medical Demobilization

SIR.—Dr Estcourt (Feb 23, p 295) argues that, because (as he thinks) the "mass demobilization"—I thank him for that word—of doctors would have suited the Government better if it had been deferred until the summer, the motive which I ascribed to them—namely, a desire to get an immediate and large recruitment of doctors for the State service—is negatived. May I submit arguments in support of my explanation of this particular timing?

Mr Bevan is obviously faced with an immense volume of resistance offered by the vast majority of the medical profession to his proposals. Your admirable leader in the *Journal* of Feb 2 underlines and stimulates this opposition.

Mr Bevan will, no doubt, have noted the cardinal mistake made by the Minister of Education in attempting "to make the Education Act work" without first securing an adequate reserve of teachers. The expedient adopted by the Minister to meet this deficiency was to admit to the national schools a vast number, estimated at about half the total required, of new recruits, who will attain the status of "qualified teachers" after a period of training from one quarter to one-half of that hitherto exacted for such qualification. Mr Bevan obviously cannot follow this precedent, but when he meets Parliament in two or three weeks with a Bill which will call for at least three times as many doctors as are now available he will be in a much stronger position than his colleague, the Minister of Education, if he can declare, as he obviously hopes to do, that he has "in the bag" some thousands of doctors suddenly released from the Forces, where they have been subjected for six years to continuous unilateral Socialist propaganda in which a State medical service has been a primary objective.

There have been five Ministers of Health in the past five years. Mr Bevan may, quite legitimately, yearn to put upon the Statute Book, before he in turn gets moved on in due course, a vast health measure which has been for fifteen years a primary objective of the Socialist Party and which will bear his name. It is Dr Estcourt not I who calls this a "dirty motive" but I have little doubt that this manoeuvre will be acclaimed by his enthusiastic supporters as a characteristically "clever" Party scoop—I am, etc.

House of Commons

E. GRAHAM LITTLE.

A Fundamental Principle

SIR—I am a laywoman, unconnected with the medical profession in any way except occasionally as a patient, but I read the *Journal* because I like it, and I have been following the recent correspondence about the N.H.I. with interest. I must confess that my impressions are not at all the same as Dr J. H. Wilson's (Feb 23, p 295). There have been many letters

from doctors, in this and other connexions, showing "real concern for the welfare of the people"—i.e., their patients. I have no doubt that many reforms are desirable in connexion with our present medical system, but when doctors resent the threat of interference in the form of ignorant and pettifogging dictatorship and niggling regulations regarding their work they are quite right. Independence of judgment and of initiative, freedom of action and personal responsibility are essential to the exercise of any of the professions, but these are just the qualities which are proverbially anathema in the Civil Service, which is generally so busily treading elaborate mazes marked out with red tape that there is not much energy or appetite left for real work. To remove the scope for the exercise of these qualities in any profession is to induce that sense of frustration which expresses itself first in anger and resentment and finally in boredom and apathy.

In this connexion I recall an observation I have heard made regarding recruitment for the Colonial Medical Service, a State service—that it does not as a rule attract the best men because the frequent transfer from district to district prevents them from taking the same interest in their work as men settled in one place can have. Enthusiasm is killed because the work begun continually has to be dropped. This applies also to school teachers in the Colonial Service.

One possible effect on patients of a compulsory health scheme where people are determined to get their money's worth and have no inducement *not* to imagine themselves more sick than they really are, has not, I think, been mentioned. This is the calling out of doctors at unreasonable times and for absurdly trivial reasons. I saw something of this in internment in Singapore recently, where the doctors gave their services free. We were a camp of about 500 women and children of all nationalities and races, increasing ultimately to 1,200, with six women doctors, mostly members of the Malayan Medical Service. They were frequently called for peremptorily at the most unreasonable times for absurdly trifling reasons and often had to put up with a good deal of rudeness from people who seemed to find their sense of importance greatly inflated by having a doctor thus at their beck and call. Nevertheless, under the immense handicaps which our prison conditions imposed they carried out their work as conscientiously and devotedly as possible and, what anyone who has been a prisoner will probably agree was still more creditable, with all the sympathy and pleasant manners which one expects from a doctor under normal conditions. We had very few women in the camp of any education or administrative ability, and, in addition to their medical work, two of the doctors—Dr Elinor Hopkins and Dr Cicely Williams—were at different times camp commandant. Dr Williams, who, under a temporary sympathetic Japanese regime which wanted to improve our diet, was taken out of camp to write a report on the food along with one or two doctors from the men's camp, was later removed from camp by the Japanese Gestapo on suspicion of contacts made with the local people during this period and spent five months in a Gestapo prison. Dr Patricia Elliott, in face of considerable opposition which included, I am sorry to say, some English women, persuaded the camp to elect a child welfare committee, part of whose work was to prevent the lower-class Eurasian mothers from brutally beating and otherwise ill treating their children.

I mention these facts only because they afford an instance of doctors' devotion to their work and their public spirit generally under especially difficult and unpleasant circumstances. Without deifying the medical profession in any way, I cannot subscribe to Dr Wilson's criticisms. I think he is too hard upon the great body of his colleagues. And as regards slum patients it is to be hoped that the Government will not forget that the first essential to improving the health is to abolish the slums. All else is merely palliative—I am, etc.

General Practitioners and Hospital Practice

SIR.—During the last six or seven years there has developed a wider conception of the hospital's sphere of work, a conception which had begun to form in many minds before the war. No longer are we content to regard the hospital as a place in which the patient is nursed through the serious part of an illness, and which takes little interest in him after recovery.

until he falls ill again. A careful follow-up in association with all the social welfare organizations is demanded in the interests of the patient and the community. It is thus evident that not only patients but hospitals need rehabilitation.

The widely prevalent idea that by centralizing hospital work in large institutions one will achieve the best medical results is fallacious, tending to stultify local effort and lessen the interest of the community in the hospital and so reduce the hospital's educative value. It seems to me that in reorganizing medical services the first consideration, contrary to the general opinion, should be improvement of the general practitioner service, which forms the first line of defence against illness. The more efficient this is the less need there will be for hospital treatment, and such cases as eventually do need such treatment will reach the hospital at a stage where they are likely to receive maximum benefit. There are many things that should and can be done to improve the general practitioner service, but probably the most important is that the G.P. should be more closely connected with the work of the hospital in his area. This could be achieved by offering clinical assistantships to G.P.s willing to serve, these to be held for a limited period by men selected from a rota.

Dr. S. Goldwater, in an article on "The Hospital, the Family Doctor, and the Patient" in *The Hospital in Modern Society*, writes:

"The physician who enjoys a proper institutional association avoids the danger of becoming careless and superficial in his clinical methods. Nothing is more indispensable to the success of any effort to restore the general practitioner to a central place in medical practice than the creation of right relations between the family doctor and the hospital. Recognition of the need of a hospital connexion for every practitioner should be a controlling factor in all community hospital organizations, for a practitioner cannot do his job competently unless he enjoys the advantages of a healthy stimulating environment."

The cry is now for centralization of cases in large institutions, where every means of diagnosis and treatment is available, but a little thought should convince one that along with certain advantages there are definite disadvantages—physical and psychological—in such plans. The influence of the psychological factor is such that treatment demanding distant separation from relatives and friends may, and often does, yield less satisfactory results than less perfect, but nevertheless good, treatment nearer home. Moreover, centralized treatment in large institutions tends to deaden the communities' altruistic efforts, which will always be necessary for the development of a really satisfactory national medical service.

Bringing the general practitioner into closer association with the hospital not only will benefit him more than any of the projected refresher courses but will in turn benefit the consultant by giving him a wider outlook, and—a not unimportant consideration—lead to a more frequent call for his services in the home to the benefit of the patient. This association will be difficult to effect if there is over-centralization of hospitals whereby the latter are removed too far from the areas in which large numbers of G.P.s practise. For their education and that of the community a good case can be made out for the retention of the smaller hospitals.—I am, etc.,

London, W.8.

HAROLD SANGUINETTI.

Chartered Society of Physiotherapy

SIR.—The plea put forward by the Chairman of Council of the Chartered Society of Physiotherapy (March 2, p. 335) for a closer co-operation between physiotherapists and the medical profession is deserving of strong support. The maintenance of the present acknowledged high ethical standard of the members of the Chartered Society is likely to become more difficult unless that co-operation be improved.

On the medical side it is to be regretted that many practising doctors and most medical students are not well informed as to modern physiotherapeutic techniques; this should be corrected by including some demonstrations and lectures on the subject in the medical curriculum.

Physiotherapists on their side should take every opportunity of showing doctors the scope and value of their methods, and multiply their points of contact with the medical profession. The Council of the B.M.A. recently had to deplore the severance

of one important link when the Chartered Society voluntarily withdrew from the Board of Registration of Medical Auxiliaries. It is to be hoped that the new medical service will provide closer links between doctors and physiotherapists.—I am, etc.,

London, W.1.

V. ZACHARY COPE.

Anaesthesia

SIR.—Dr. W. A. Bellamy's letter (Feb. 16, p. 252) betrays an attitude of mind not uncommon to many who find it easy to preface their remarks by the phrase "twenty years ago." One begins to suspect a reluctance on their part to admit the inevitability of progress. Surely our students are taught according to the ideas of their teachers, and they by virtue of their knowledge and experience are best fitted to advise as to the curriculum.

The plain fact is that the "good enough" in anaesthetics or any other branch of medicine will not satisfy those who seek to reach higher standards. The soldier to-day is not asked to become proficient in the use of bow and arrow ere he is taught the intricacies of the machine-gun. Let us treble the trappings, tubes, taps, and turncocks if by doing so we may reduce the mortality by the merest fraction. Might we not greatly improve the morbidity rate in our efforts? The death rate is surely not the only criterion. Avertin, originally introduced as a general anaesthetic, proved too deadly an agent but found a useful place as a basal anaesthetic. If the pundits now seek to prove its undesirability as such we must be broad-minded enough to entertain opinions, though these may run contrary to our own. Let professional conscience be our guide.

Who, for one moment, would suggest that the art of anaesthesia is a "mysterious cult," etc.? To practise the art, however, requires effort and a willingness to learn and understand how difficulties may be avoided and overcome, also an obligation to admit one's faults in any technique, no matter how cherished that may be, should other and more observant eyes detect such faults. Twenty years after or forty years after, let us never be too old to learn.—I am, etc.,

Salisbury.

A. D. H. SIMPSON.

The Services

I.M.S. Dinner

The annual dinner of the Indian Medical Service is being revived this year. It will be held at the Connaught Rooms, Great Queen Street, W.C., on June 19. Major-Gen. Sir E. W. C. Bradfield will preside, and applications for tickets may be sent to Major-Gen. R. H. Candy, c/o Grindlay and Co., Ltd., 54, Parliament Street, S.W.1.

Col. (Local Brig.) D. Fettes, O.B.E., late R.A.M.C., has been appointed Honorary Surgeon to the King in succession to Major-Gen. D. C. Monro, C.B., C.B.E., late R.A.M.C., retired.

Surg. Cmdr. R. W. H. Tincker, R.N.V.R., has been awarded the R.N.V.R. Officers' decoration.

Surg. Lieut.-Cmdr. H. G. Singer, R.N., has been mentioned in dispatches for good services while a prisoner of war.

The following appointments and mentions in dispatches have been announced in recognition of gallant and distinguished services in the field:

C.B.E. (Military Division).—Brig. (Temp.) W. M. Cameron, O.B.E., R.A.M.C.

M.B.E. (Military Division).—Capt. G. Forrest-Hay, R.A.M.C. Mentioned in Dispatches.—Major (Temp.) D. E. O'Connor-Cuffey and Capt. G. F. A. Caldwell, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—Capts. Patrick James O'Flynn and Bernard Sidman, R.A.M.C.

Died.—Major A. P. Barnard, R.A.M.C.; Major W. Bornshin, I.M.S.

Previously reported missing, now reported killed.—Lieut. A. E. Lewis, I.A.M.C.

Previously reported missing, now reported died of wounds.—Capt. S. S. Kirtane, I.M.S.

Previously reported missing, now reported died while a prisoner of war.—Capt. Godwin Lionel Robbins Tapsall, I.M.S.

Wounded.—Capt. S. Bradshaw, Lieut. A. R. Brailsford, Capt. Marguerite E. M. Day, Capt. H. W. Holland, R.A.M.C.; Capt. I. S. Dalson, I.A.M.C.

Obituary

J G PORTER-PHILLIPS, M.D., F.R.C.P.

We announce with regret the death on Feb 24 of Dr John George Porter Phillips for many years physician superintendent of Bethlem Royal Hospital and physician for and lecturer in psychological medicine at St Bartholomew's Hospital.

Son of the late Robert Phillips, he was born in India, at Darjeeling, on June 28, 1877, and was educated at Brighton, at University College, London, and at Guy's Hospital. He graduated M.B., B.S. London in 1907 and, after holding house appointments, won the Gaskell gold medal and prize in psychology and psychological medicine in 1911, he took the M.R.C.P. in 1914 and was elected F.R.C.P. in 1922. From 1910 onwards Porter Phillips contributed a number of valuable papers on medical psychology, noteworthy among these being an address to the Hunterian Society in 1922 on "Insanity and its Relation to Criminal Law," and a paper in the *Lancet* on "The Early Treatment of Mental Disorder: A Critical Survey of Out-patient Clinics." Soon after his appointment as head of the Bethlem Hospital on its old site in Kennington he became lecturer in mental pathology at the London School of Medicine for Women, before then he had been the principal medical officer to King Edward School, Witley. During his very long membership of the Royal Medical Psychological Association he acted for a time as educational secretary and as examiner for its diploma, he also examined in mental diseases for the Royal College of Physicians and at the Royal Army Medical College. His appointment to the senior staff of St Bartholomew's brought him into human touch with a long succession of students who attended his lectures and clinics there and also visited the Bethlem Hospital.

J.G.H. writes: Dr Porter Phillips was a handsome man with a charming manner and a sympathetic attitude which made him very popular with his patients. He was always dignified, and his calm distinguished bearing gave confidence to worried people, so that for many years he had a large consulting practice. Bethlem was his greatest interest and he was responsible for many advances and innovations there. In 1922 he started in Lambeth one of the first psychiatric out-patient departments in the metropolis. In 1930, when the new Bethlem Hospital at Monks Orchard was opened, many of the improvements which it possessed were his suggestions.

One of his interests was a dining club composed of medical men who had worked at Bethlem, this had quite a large membership since the hospital has for many years had house physicians who were appointed for six months, many of these remained in psychiatry and, before the war, enjoyed coming to London for an annual reunion. He was responsible for the production of a hospital magazine and was himself a contributor to it. The war and the alteration in the manner of living came as a great change to him, but he remained at his post beyond the ordinary retiring age, until the end of 1944, when he was made a governor of the hospital. He will be mourned by a large number who have known him. He leaves a widow, two married daughters, and a son.

JOHN DAVIS BARRIS, M.B., F.R.C.P. F.R.C.S., F.R.C.O.G.

All St Bartholomew's men will learn with great regret of the death of Dr John Barris, which took place in the hospital on Saturday, Feb 23.

John Barris was born in 1879 and in 1898 he entered Caius College, Cambridge, where he received an honours degree in Arts in 1901. As an undergraduate at Cambridge he took an active part in boxing and other sports. He then came to St Bartholomew's Hospital, and while still a student was awarded the Shuter Scholarship. He qualified in 1905, and in 1908 was chosen for the Luther Holden Research Scholarship. At this time he was a member of the junior staff and in this capacity he served as house surgeon to Mr W. Bruce Clark and then in turn midwifery assistant to Sir Francis Champneys and Dr W. S. A. Griffith. After that he served as tutor to the department from 1909, the year in which he obtained the F.R.C.S.

to 1913, when he was elected to the staff of the hospital. During the first German War he served with the R.A.M.C. in France. In 1925 he was elected F.R.C.P. and became senior physician accoucheur and head of the department, which post he held until he retired in 1939 under the age limit. He was then made consulting physician accoucheur and a governor of the hospital. When war broke out he immediately volunteered to help again in the department and worked at St. Albans until 1945.

John Barris was a born teacher, and in this respect showed himself a worthy successor to Herbert Williamson. He had a wonderful fund of patience and never tired in his efforts to drive home the details of sound midwifery. He was a member of the Obstetric and Gynaecological Section of the Royal Society of Medicine, and in 1938 was nominated as president of the Section, but he decided to refuse the honour because he was not in sufficiently good health to devote his best work to it. He was joint author of several textbooks, including *Midwifery by Ten Teachers*, and also *Diseases of Women by Ten Teachers*.

In 1909 he married Margaret Morris and they had three daughters. Throughout his career at St. Bartholomew's Barris was intensely keen about the hospital rugby football club, and was its president for twelve or more years. Many of his best house surgeons were also the best rugby players for the hospital. Barris was an exceedingly modest person, and much that he did for the hospital went unrecorded. His kindness and good temper were proverbial and he was never known to lose his calmness even in the greatest emergency. There never was a man who was more loyal to his junior colleagues, by whom he will be sadly missed.

M.D.

Surg. Lieut. J. B. Gurney Smith, R.N.V.R., writes

As an old obstetric student of Barris's may I pay tribute to a very revered teacher. Of all my clinical instructors, I feel none excelled Dr Barris as a teacher. His lectures and ward rounds were invariably a sheer delight, and one never came away without feeling inspired. His painstaking preparation of his lectures was self-evident, and those who heard it will not soon forget his discourse on breech presentation. Perhaps two of his most marked qualities were his humanity and his devotion to Barris. How often on his round in Martha Ward would he say, "Gentlemen, we are not considering a case of fibroids, but a woman who has a fibroid." To hear him talk to a patient was an impressive example of the authentic clinical approach. To be one of his clinical clerks was indeed an education and a privilege. In my first term as a pre-clinical student he was president of the Students Union. His welcoming address to its freshmen at the Students Union social, in which he extolled the grandeur of the hospital into whose life we were just entering, still lives in my mind. His reference to the famous "Square" with its celebrated fountain as "the soul of Barris's" was I felt, a peculiarly apt phrase. His ready smile, his slow gait, and his courteous dignified manner all left an indelible impression on the mind.

SIR UPENDRANATH BRAHMACHARI, M.D.

By the death on Feb 6 in Calcutta of Sir Upendranath Brahmachari at the age of 70, Bengal has lost one of her most distinguished Indian medical graduates. He was educated at the Hooghly College, where he obtained high honours in mathematics on taking the B.A. degree of Calcutta University in 1893, he entered the Calcutta Medical College after taking a degree in chemistry in 1894 and passed the M.D. examination in 1898, with the first place in medicine and surgery. This led to his early selection as a teacher in the Dacca Medical School and subsequently as lecturer in medicine at the Campbell Medical School. There he worked for nearly twenty years and built up a reputation as a physician and research worker with a lucrative practice. He retired in 1927 after having been physician to the Carmichael Medical College Hospital.

He will best be remembered for his researches on the treatment of kala azar, for after tartar emetic, a trivalent antimony compound, had been proved by Italians and by workers in India to be a reliable cure for kala azar Sir Upendra turned his attention to pentavalent antimony compounds and found that urea-stibamine was more reliable and rapid in its action than potassium and sodium tartrates. Search for pentavalent compounds was at the same time being carried on by European chemists, the most successful of which was found, a work in the Calcutta School of Tropical Medicine, to be most basic.

Kala-azar was still prevalent in Assam, where the medical authorities used urea-stibamine on a large scale with marked success. Later Sir Upendra introduced the intramuscular use of neostibene. His clinical acumen was shown in his being the first to describe dermal leishmaniasis. In 1928 he published a book on kala-azar, and in 1940 two volumes entitled *Gleanings from my Researches*, together with very numerous papers and articles and addresses. He was knighted in 1934.

As a result of these researches honours followed thick and fast; of these the following are the more important. He served for long as Dean of the Faculty of Medicine, University of Calcutta. At different times he was president of the Indian Science Congress, of the Asiatic Society of Bengal, the Indian Chemical Society, the Society of Biological Chemists, India, of the Medical Research Section of the Indian Science Congress, and of the Board of Studies in Medicine, Calcutta University. During the recent war he held office in the Indian Red Cross Society, and became the first Indian chairman of its Bengal branch; he was also a vice-president of the St. John Ambulance Association, Bengal Centre. He served on the Board of Industries, Bengal, and on the Board of Trustees of the Indian Museum. At one time he was honorary assistant surgeon to the Viceroy. He received medals for his researches from Calcutta University, the Calcutta School of Tropical Medicine and Hygiene, and the Royal Asiatic Society of Bengal, and the Kaisar-i-Hind gold medal. Thus the promise afforded by the outstanding successes of his academic career was amply fulfilled by the proficiency he showed throughout his long medical service, aided by indefatigable energy and perseverance, which was crowned by his discoveries regarding the treatment of kala-azar. His successes have rarely been equalled, and never surpassed, by his Indian contemporaries, and his example will be a stimulus to his fellow-countrymen in labouring for the good of vast but poor races of India shortly to be committed to a fuller extent than ever to their care.

Dr. H. P. LIE, of leprosy fame, died on Dec. 17, 1945, the day before he was due to celebrate his 83rd birthday. He was for many years the understudy of Dr. Armauer Hansen, who discovered the bacillus of leprosy in 1873 and who, on his death in 1911, was succeeded by Lie as the administrative head of the leprosy services in Norway. Lie lived up to his favourite rule: "As we are a small nation, quality must take the place of quantity." The quality of Lie's work was such that he became a universally recognized authority on leprosy, and it fell to his lot to organize the International Leprosy Congress, presided over by Armauer Hansen and held in Bergen in 1909. In spite of the many claims made on him at home and abroad in connexion with leprosy, Lie found time to serve on the Municipal Council of Bergen, to promote the scientific work in the Bergen Museum, and to preside over the Norwegian Society for the Promotion of Science. He was also an associate editor of several scientific publications.

The death took place on Jan. 12 of Col. MICHAEL J. WHELTON at the Mount Vernon Hospital, Middlesex. Born in 1892 at Cork, where he received his early education, he entered University College, Cork, and graduated in 1916 with first-class honours. After a year at hospital work in London he joined the R.F.C., served in France, and later was posted with the Army of Occupation on the Rhine. In 1920 he entered the R.A.M.C., graduated M.D. in 1926, and took the D.P.H. in 1928. He served in India, China, Egypt, and Palestine, and again in France in 1939-40. In 1942, though already having had treatment for the malady which later proved fatal, he went to North Africa in command of the 70th British General Hospital, and working ceaselessly in Africa, Sicily, and Italy, was an inspiration to his colleagues and was justly honoured by his superiors and mentioned in dispatches. Ill-health made a return to London for treatment imperative in July, 1945. W.M.C. writes: Col. Whelton commanded the 70th General Hospital in Africa, Sicily, and Italy with the same simple naturalness which he put into every part of his life. What mattered to him was the man and not the uniform he wore, and many will remember with gratefulness his sympathetic understanding. He abhorred pomposity and laziness, but no one was quicker to recognize genuine endeavour and skill. His one thought was the good of the unit and the efficiency of the service it gave, and, compared with these, Army regulations were of minor importance. His knowledge of tropical medicine and his enthusiasm for hygiene were of great value in the unit. He was a man of genuine kindness and he was a loyal friend.

Dr. JOHN ALEXANDER PRINGLE, honorary ophthalmic surgeon to the Kent and Canterbury Hospital, who died at Epsom on Feb. 12, was born at Aughnacloy, Co. Tyrone, in 1882, and was educated at Coleraine Academy, at the Royal Academy, Belfast, and at Trinity College, Dublin. He graduated in medicine in 1905, and proceeded M.D. of Dublin University in 1908 after holding house appointments in Dublin and at the Bristol Eye Hospital. Coming to London he worked as chief assistant at Moorfields and senior ophthalmic assistant at St. Mary's Hospital, and later settled at Canterbury. During the war of 1914-18 he was officer in charge of the ophthalmic centre at Rouen, and then ophthalmic surgeon to the 4th Army, B.E.F., and afterwards held the same post in the British Army of the Rhine. On returning to civil life he became eye surgeon to the Ministry of Pensions for the Canterbury District and to the local education authority; he was also consulting ophthalmic surgeon to the Herne Bay Hospital and to Princess Mary's Hospital for Children at Margate.

Medical Notes in Parliament

Medical Examination for Industrial Injuries

On Feb. 18 the House of Commons discussed the National Insurance (Industrial Injuries) Bill after its amendment in a standing committee. On Clause 25 (obligations of claimants and beneficiaries) Mr. DOUGLAS moved to omit the provision that the injured person must accept the treatment appropriate to the relevant injury or loss of faculty. He said that as the clause was drafted the Minister was given power to make regulations determining the treatment appropriate, and would presumably have power to make regulations obliging an injured person to attend before a doctor whom the Minister chose. That doctor would prescribe a course of treatment. By a later part of this clause the Minister had power to oblige the injured person to observe that course of treatment, and in subsequent clauses to deprive the injured man of benefits if he did not have the course of treatment prescribed. The Minister further had power to make regulations which would impose upon the claimant a liability to pay £10 a day for every day during which he refused this treatment. The definition of treatment included surgical treatment and amputations and could also include inoculation.

Mr. HOUSE, seconding the amendment, said the B.M.A. was seeking freedom of choice for the patient as between one registered medical practitioner and another and also freedom of choice for doctors to enter Government service or private practice. Mr. House asked that the injured workman should have freedom of choice to attend either a registered medical practitioner or an unorthodox practitioner such as an osteopath, naturopath, herbalist, or others. He spoke as a layman who had benefited by "nature healing." Unorthodox practitioners were prepared to deal effectively and in an organized manner with quacks. He and his friends only wished those unorthodox medical practitioners to be recognized who could comply with whatever standard qualifications the Minister might lay down.

Mr. PAGET said the Workmen's Compensation Act contained a similar provision to that which was now challenged. Under that Act the doctors of insurance companies used to go into the witness box and say: "This man will be cured by operation." In the large majority of cases in which, in his practice under the Act, he had known the man to submit himself to operation the medical advice turned out to be quite wrong.

THE OBJECTIVE OF EXAMINATION

The SOLICITOR-GENERAL (Sir Frank Soskice) said the penalty clause of the Bill empowered the Minister to make it an offence not to comply with the regulations. The Minister never intended to prepare a regulation which would make it an offence punishable by the criminal law for any workman to fail to comply with directions given under a regulation. The Government proposed to accept on a later clause an amendment which would provide that it should be an offence not to comply with a regulation other than one requiring a workman to submit to medical treatment. The proposal in the clause under discussion was simply that when a workman submitted himself to medical examination the first object of that examination should be to determine the effect of the relevant injury. The second object would be to enable the Ministry's doctor to try to make up his mind what treatment would be appropriate to the injury. That was a primary purpose of all medical examinations. If the man without reasonable cause refused to accept the advice of the doctor all that could happen to him would be that he forfeited his right to benefit. If a workman held strongly the opinions voiced by Mr. House the insurance officer to whom the case could be referred might take the view that such opinions were a reason-

able cause. The regulations which the Minister proposed to make must be submitted to the Industrial Injuries Advisory Council, which would include experts qualified to judge of these matters. The Solicitor-General submitted that the injuries with which the Bill would deal were, in the majority of cases, diseases that were known or the causes of which would not give rise to a great deal of medical controversy. He asked the House to reject the amendment.

Dr. H. B. MORGAN said a great deal of the antimedical prejudice was the aftermath of conditions when workmen in the past had been examined by a particular set of doctors whose object had always been to see whether the man was malingering or whether he was trying to prove that his physical injury or disease was due to an accident when the Ministry of Pensions held that it was not. Hitherto assessment of disability resulting from disease or accident had not been taught in British medical schools, but even if what had been said was true, the workman was entitled to the best professional medical treatment he could get. No untried treatment was sufficient. Dr. Morgan failed to see why any scheme to which all workers contributed should not lay down regulations for the appropriate treatment for every individual on a broad scale. If the Minister of National Insurance secured the right type of medical man to do this work he would confer great benefits on the workmen. Dr. Morgan hoped there would be machinery to secure the right type of doctor.

THE "COMPENSATION DOCTOR"

Mr. JAMES GRIFFITHS, replying to the discussion, said that in the past a man receiving an injury was asked by the employer to attend at a certain place to be examined by a man who was known as a "compensation doctor," partly or fully employed by insurance companies and others and not strictly employed for purely medical purposes. Under the present Bill the Government took power to enable the medical officer acting for the Ministry to require the man to be examined in order to suggest and advise proper treatment. Obviously the Ministry would have its own doctors and the man would have his doctor, and there would be consultation between the two. Most of the cases concerned would be of physical injuries or industrial diseases. For the first time in a workmen's compensation Act it would be the concern of the Government to see not only that a man received what he was entitled to receive but also that he was encouraged and advised to secure treatment.

Dr. MORGAN asked where, pending the development of a National Health Service, the Minister would find rehabilitation centres for the men whom he intended to compel to have certain treatment. Mr. GRIFFITHS replied that the Government could not provide a full scheme at present. In the meantime they had a miners' rehabilitation centre in South Wales.

Sir HENRY MORRIS-JONES said that at present a man could appeal to a judge of a court of law who had two medical men as assessors. Under the proposal before the House the man who disagreed with the Government's doctor about treatment prescribed must appeal to an insurance officer—a layman—who would have to decide a purely medical issue.

The amendment was negatived.

Mr. DOUGLAS moved to leave out the provision that an injured man for whom treatment had been prescribed should be bound to observe "any prescribed rules of behaviour." He pointed out that acceptance of this amendment would still leave the condition that the man was "not to behave in any manner calculated to retard his recovery." The Solicitor-General said he could not accept the amendment, claiming that a subsequent amendment put down by the Government would meet the point. Later, after some discussion, he announced that the Government had decided to accept it.

When the debate was resumed on Feb. 19 Mr. GRIFFITHS, on Clause 56 (special provision as to certain respiratory diseases), moved to substitute six for three months as the period during which a man who was certain to become disabled if he remained at work could be suspended by a medical board from employment in a coal mine. He said everything should be done to prevent men staying in the mines after the onset of pneumoconiosis or silicosis. Six months itself was a short enough period.

Dr. BARNETT STROSS said those interested in the subject were happy to have this extension. However, if they waited until the first stage of silicosis was well established and then gave six months' entitlement they would not do much. The Minister must see that the periodical medical examinations were frequent and thorough enough to enable men to be withdrawn at a very early stage. The men should come out in what the South Africans used to call the "ante-primary stage." Dr. MORGAN advocated no limitation of time to either three or six months. Men should receive payment if regarded as fit for suspension until they were rehabilitated to the extent of finding other jobs at which they could work.

Mr. JAMES GRIFFITHS said that all the Government was doing was dependent on the completely new and successful health service. There must be "periodical examination of the men all the time." That would be done as soon as possible, but it could not be done now.

Dr. MORGAN appealed for the power of certification to be extended to cases of men suffering from pneumoconiosis through dust caused in foundries. He said this had not been accepted by the Government on the ground of insufficient evidence. Mr. GRIFFITHS said power had been granted to a board to decide this problem. He could not accept responsibility for the suspension of men.

The amendment moved by Mr. Griffiths was accepted. After further discussion and amendment the report stage was then completed.

Medical Recruitment

Asked by Mr. ALLIGHAN on Feb. 26 what had been the distribution of recruits to the medical branches of the three Services since June 18, 1945, Mr. BEVAN said the totals were: Navy (to Feb. 25) 105, Army (to Jan. 31) 433, R.A.F. (to Jan. 31) 33.

Col. STODDART-SCOTT on Feb. 28 asked Mr. Bevan to distribute to the R.A.F. a larger number of medical recruits so that demobilization would not remain ten groups behind the Army. Mr. BEVAN said he was aware of the delay in demobilization of medical officers from the R.A.F. The allocation of doctors to the R.A.F. had been reviewed on the previous day by the Medical Personnel (Priority) Committee. He promised to consider the matter in the light of any recommendations the committee might make.

University Grants

Mr. DALTON announced on Feb. 22 that he proposed to ask Parliament to vote £9,450,000 for grants to the universities for 1946-7. This was £3,800,000 more than had been voted for 1945-6. It included a further £2,250,000 for capital grants, a re-vote of £1,200,000 which had not been spent, and an additional £100,000 for dental education. He had told the University Grants Committee that he would be prepared, if good cause were shown, to ask Parliament to vote even larger capital sums.

On the same date Mr. GLENVILLE HALL stated that the constitution of the University Grants Committee was as follows: Sir Walter Moberly (chairman), Prof. W. E. Collinson, Sir Charles Darwin, Miss Margery Fry, Sir Robert Greig, Sir Peter Innes, Sir Frederic Kenyon, Prof. P. S. Noble, Prof. G. W. Pickering, Prof. Andrew Robertson, Sir Edward Salisbury, Prof. J. C. Spence, Prof. R. H. Tawney, and Sir Henry Tizard. The members were not appointed in a representative capacity, but the committee was so constituted as to include persons with special qualifications and experience in the main fields of university activity.

Hospital Accommodation in Scotland

Mr. Westwood told Major Guy Lloyd on Feb. 26 that action on the observations contained in the recent survey of Scottish hospitals by the Department of Health for Scotland would generally have to await the reorganization of the health services as a whole. The first concern of the local authorities responsible for tuberculosis and infectious diseases would be to remedy shortages of nursing staff, so that all the accommodation already available could be used.

Harvard Field Hospital Unit

On Feb. 25 Major J. Morrison asked the Minister of Health if, in view of the difficult housing situation in Salisbury, he would arrange for the Hubbard hospital buildings recently vacated by the U.S. Army to be made available as temporary accommodation. Mr. BEVAN assumed that Major Morrison referred to the Harvard Field Hospital Unit, which was generously presented to Britain during the war by the American Red Cross and Harvard University for the purpose of research into the prevention of infectious diseases. Mr. Bevan said he intended this should continue to be used for purposes allied to that of the original gift.

Ambulance Ships.—Two vessels fitted as ambulance transports are engaged in transport of sick and wounded Service men to the United Kingdom. Mr. LAWSON on Feb. 26 refused to accept the suggestion that the degree of comfort and the facilities provided on these ships were inadequate for the purpose. He added that hospital ships were still used for the transport of the more seriously ill patients. He pointed out that it was not the normal peacetime practice to carry invalids in hospital ships, as the numbers were too small.

Dental Benefit.—The Dental Benefit Council, which is representative of dentists and approved societies, will meet on Feb. 14 and will consider an application for a revision of the scale of fees.

prescribed by the Dental Benefit Regulations. Mr. James Griffiths hopes that in the result a solution will be found of the difficulties arising out of the refusal of certain dentists to undertake work on the basis of the present scale of fees. The question of resuming regular meetings of the council will also be considered.

Hospital Domestic Labour.—When asked on Feb. 21 about a shortage of domestic workers at Colindale Hospital, Mr. ISAACS said the British Hospitals Association and other hospital associations had contributed to building up standards for this work which should encourage further recruitment. An understanding about wages and working conditions had been put into force. Until the Ministry saw how a publicity scheme for encouraging people to take up these duties was working he was not going to arrange wholesale importation of domestic workers from the Continent.

Tuberculosis Invalids from the Navy.—Between September, 1939, and January, 1946, 8,144 officers and ratings, including Royal Marines, were finally invalided out of the Royal Navy on account of pulmonary tuberculosis.

Hot-water Bottles.—Sir STAFFORD CRIPPS said on Feb. 18 that retailers had no authority to demand medical certificates before supplying hot-water bottles. But if, in the opinion of the patient's doctor, a rubber hot-water bottle was necessary for purposes of treatment, it was desirable that a medical certificate should be given some priority. Certificates should be issued only on that ground.

The Aged and Extra Milk.—Sir Ben Smith will not authorize doctors to issue certificates for extra milk for old people not suffering from specific illnesses. The Special Diets Advisory Committee of the Medical Research Council advises him that there are no nutritional grounds for allowing extra milk to old people. He has arranged for repatriated civilian prisoners of war who were suffering from malnutrition to be allowed extra milk.

Notes in Brief

Up to the end of December last pensions had been granted in about 3,000 cases of psychosis and 1,000 of epilepsy accepted as attributable to or aggravated by service in the war. In addition awards had been made in about 27,000 cases of psychoneurosis and other nervous disorders.

Calcium in the form of creta praeparata is added to flour at the rate of 7 oz. of calcium to 280 lb. of flour.

The Minister of Food states that he has made arrangements for people suffering from coeliac disease to be able to get ample and regular supplies of dried bananas. His medical advisers inform him that these are as suitable for such patients as fresh bananas. He does not propose to make any special arrangements for them to get fresh bananas. It would not in any case be possible to guarantee regular supplies.

The report of the Electro-acoustics Committee on Hearing Aids is being prepared. It is hoped to publish it in the near future.

The Minister of Supply, Mr. Wilmot, is doing all he can to help manufacturers to secure skilled labour for manufacture of surgical apparatus such as spinal jacks.

There is no prospect of soap rationing ending at an early date.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation on March 1 the Senate resolved to confer the degree of Master of Arts, *honoris causa*, upon Arthur Leslie Banks, M.D.Lond., Principal Regional Medical Officer of the Ministry of Health. The recommendations of the Council of the Senate for the establishment of a professorship of radiotherapeutics were approved, and also for an additional payment to the Regius Professor of Physic for work in connexion with the organization of the School of Clinical Medicine.

The Board of Management of the Frank Edward Elmore Fund will shortly award a studentship for research, open to male graduates of any university in any country, who were born at any place within the British Empire, other than Scotland. The student appointed will work in the Department of Medicine at Cambridge, under the direction of the Regius Professor of Physic, commencing salary £400 a year, the appointment being for two years in the first instance. Further information may be had from the Regius Professor of Physic, Department of Medicine, University of Cambridge, to whom applications, with three testimonials, a statement of previous appointments, and copies of published papers, should be sent so as to reach him by March 22.

The following candidates have been examined and approved for the degree of M.Chir.: A. G. Leacock, G. C. Martin, B. H. Page.

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—J. C. Millichip (with honours and distinguished in surgery), Daphne S. A. Anderson, H. Annamunthodo, E. R. Arnold, R. J. Aspinall, P. T. Ballantyne, J. C. Batten, A. J. Beale, D. W. Beynon, Margaret J. Blair, L. W. Bland, Pattie E. Bradfield, Catherine M. P. Bradstreet, P. E. Brown,

G. H. Carrick, H. E. A. Carson, P. T. Chopping, C. I. Cooling, B. S. Cooper, W. D. Corfield, J. C. Crook, Naami Datta, E. T. De Mel, H. G. Dixon, C. J. Don, F. R. Ellis, Norah C. Elphinstone, Rosemary F. Evans, Elizabeth P. E. Everard, A. Feldman, H. Fishbone, A. Folkson, S. L. Gauntlett, Jean M. Gilbert, Beryl M. Goetzee, L. S. Goodhardt, W. P. D. Green, W. P. Gurrass, D. O. Haines, Audrey Hanson, Elizabeth J. Harman, P. C. Harris, T. A. Harrison, A. Hollman, T. G. Hooson, Edith C. C. Hörburger, J. R. F. Innes, H. C. W. James, B. W. Jaslowitz, R. C. Jennings, K. S. Jones, J. W. Jordan, P. K. S. Joynton, D. L. Kerr, I. W. Kerr, Catherine M. R. Kirkpatrick, J. M. Kodicek, T. Koonvisal, E. Kupfer, E. T. Lay, Elizabeth J. Lee, B. Lewis, S. Lewis, O. C. J. Lippold, Anne Maguire, L. V. Martin, D. T. Methuen, J. B. Musgrove, Rosemarie D. Newhouse, J. K. Oates, D. J. O'Brien, H. Parkes, Liliane Parkinson, T. D. Parsons, I. C. L. Patch, I. A. W. Peck, G. F. Penny, J. H. S. Pettit, G. D. Powell, D. E. Pugh, S. S. Raphael, Rosalind B. Reiss, A. T. Richardson, L. Roodyn, M. L. Sacks, A. H. Saddler, M. E. Samrah, T. A. L. Scott, G. C. W. Sharpe, C. S. Shaw, L. Silverstone, E. R. Simpson, S. R. Sims, Mary E. Smith, K. A. Sowden, D. G. H. Sylvester, B. E. R. Symonds, Edith Taylor, E. H. Taylor, Mary J. L. Taylor, G. I. Tewfik, Vivian M. N. Usborne, Brenda D. van Leuven, J. D. Wallace, J. G. Watt, P. Westcombe, M. J. Whelan, J. B. Wild, J. M. Wilks, N. A. F. Young, D. M. Zausmer.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The Sydney Ringer Memorial Lecture will be delivered by Prof. J. Z. Young, F.R.S., in the Lecture Theatre of the University College Hospital Medical School (University Street, Gower Street, W.C.) on Tuesday, March 12, at 4.30 p.m. His subject is "Effects of Use and Disuse on Nerve and Muscle." The lecture is open to all qualified practitioners and medical students.

UNIVERSITY OF MANCHESTER

The following appointments are announced: *Lecturer in Medical Neurology*, G. G. E. Smyth, M.D. *Lecturer in Neurosurgery*, R. T. Johnson, M.B., F.R.C.S. *Lecturer in Surgery*, R. L. Holt, M.D., F.R.C.S. *Demonstrator in Experimental Physiology*, M. G. Saunders, M.B., Ch.B. *Lecturers in Preventive Medicine*, C. Metcalfe Brown, M.D., D.P.H., and F. R. Marshall, M.D., D.P.H. *Lecturers in Industrial Health*, F. H. King, M.D., A. T. Jones, M.D., D.P.H., M. W. Goldblatt, M.D. *Assistant Director of the Routine Section in the Department of Bacteriology*, H. W. Clegg, M.D., D.P.H.

UNIVERSITY OF EDINBURGH

At the February meeting of the University Court, with the Principal, Sir John Fraser, presiding, it was announced that the Cameron Prize in Therapeutics for 1946 had been awarded to Prof. A. Szent-Györgyi, of the University of Szeged, Hungary, in recognition of his eminent contributions to knowledge of vitamin C.

Robert James Kellar, M.B.E., M.B., Ch.B., F.R.C.S.Ed., F.R.C.O.G., has been appointed to the Chair of Midwifery.

UNIVERSITY OF DUBLIN

The Senate of Dublin University has announced its intention to confer a number of honorary degrees, including the Sc.D. on Sir Alexander Fleming, F.R.S., professor of bacteriology at St. Mary's Hospital Medical School, and Prof. Eric K. Rideal, D.Sc., F.R.S., of the chair of colloid science at Cambridge University; and the M.D. on Sir Herbert Eason, F.R.C.S., President of the General Medical Council.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following letter dated Feb. 14 (John Hunter's birthday) has been received by the President of the Royal College of Surgeons from Sir William H. Collins:

"I have been disturbed for some time because it seemed to me that possibly financial considerations were preventing the Royal College of Physicians transferring their headquarters to Lincoln's Inn Fields. In order to help to remove any such difficulty which may be standing in the way of the establishment of a Medical Academic Centre in London, I am making a further gift of £100,000 to the Royal College of Surgeons to provide increased endowment for the Scientific Departments. The gift is made on condition that the Council offers all the sites and property which they own to the east of the College and which are not required for the extension of the Royal College of Surgeons as a free gift to the Royal College of Physicians. The offer by the Royal College of Surgeons must be conditional on the site being used for a new building for the Royal College of Physicians and must be kept open for at least twelve months."

The Council of the College has accepted with extreme gratitude the conditions laid down and has made a formal offer of the site to the Royal College of Physicians in accordance with Sir William Collins's wish.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on Feb. 5, with the President, Dr. D. M. Lyon, in the chair, Dr. D. M. F. Batty (Edinburgh), Dr. J. Halliday Groom (Edinburgh), Dr. G. A. G. Peterkin (Edinburgh), Dr. James Innes (Edinburgh), Dr. Angus MacNiven (Glasgow), and Dr. J. S. Fulton (Glasgow) were introduced and took their seats as Fellows of the College.

Dr. B. S. Bindra (Karachi, India) and Dr. O. Olbrich (Edinburgh) were elected Fellows of the College.

No. 7

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 16.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 125 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1946					1945 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ 1 case imported.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the chief features of the returns were the large decreases in acute pneumonia, scarlet fever, and dysentery, of 445, 102, and 82, respectively. The only diseases with an increased incidence were measles, with 278 more cases, and whooping-cough, with 76 more.

Acute pneumonia was less prevalent in most areas of the country, the only exception being a slight rise in Lancashire. The fall in scarlet fever was mainly contributed by two areas—Lancashire and London—with 58 and 34 fewer cases, respectively. The only variations of note in the returns of diphtheria were reported from Wales; in Glamorganshire the cases rose from 14 to 28, and in a local outbreak in Carmarthenshire, Llandilo U.D., the cases increased from 3 to 18. Measles is only prevalent in four counties—Lancashire, London, Norfolk, and Suffolk. The notifications in these counties amounted to almost three-quarters of the total for the country.

The outbreak of dysentery in Leicestershire continued to diminish, only 23 cases being reported during the week. Other large returns for dysentery were: Lancashire 44, Warwickshire 27, London 14, Northamptonshire 13, Yorks West Riding 12, Bedfordshire 11, Northumberland 11.

The births recorded in the first seven weeks of the year in the great towns show a substantial rise on those of the corresponding period of last year—50,899 against 47,844. Despite the increase in births, the number of infant deaths are fewer—3,243, compared with 3,520.

Two liners have recently arrived from Bombay with smallpox cases aboard—the *Duchess of Richmond* with 4 cases, and the *Georgic* with 1. (According to a Press statement of March 6, the *Georgic* case is one of chickenpox.) Another case of smallpox has been confirmed in the Tilbury area; so far there have been 5 cases, with 2 deaths.

In Scotland the only diseases with a larger incidence were scarlet fever, with 26 more cases, and whooping-cough, with 22 more. A decrease was recorded for acute primary pneumonia of 104, measles 29, diphtheria 25, and dysentery 24.

In Eire measles notifications decreased further, from 85 to 57. Notifications of diphtheria rose by 16, while whooping-cough fell by 23.

Vital Statistics, 1945

The provisional returns for England and Wales for 1945 show a decline in the birth rate, the rate for the year being 16.1 per 1,000, compared with 7.5 and 16.2 for the two preceding years. Stillbirths represented 2.8% of the total births—the lowest rate ever recorded. The general death rate was 11.4—a new low record. The previous lowest death rate was 11.5 in 1942.

Typhoid in Germany

Each week in the British zone 70 Germans are dying of typhoid fever, according to the recent medical survey.

Bovine Tuberculosis

The incidence of bovine tuberculosis is unknown, and indirect estimation based on non-pulmonary tuberculosis is generally used for comparative purposes. Non-pulmonary tuberculosis is not a highly satisfactory index since many cases are of human origin, although, on the other hand, some cases of pulmonary tuberculosis are of bovine origin. For children under 5 years of age it has been found by laboratory examination that abdominal tuberculosis is nearly always of bovine origin. These deaths therefore give the best indication of the prevalence of bovine disease for comparative purposes. The following table sets out the trend of the death rates for degree of urbanization.

Death Rates from Abdominal Tuberculosis per 1,000,000
Children under 5 Years of Age in Each Area
(Actual Number of Deaths in Parentheses)

	1921	1930	1938	1944
London (administrative county)	136 (51)	24 (8)	12 (3)	6 (1)
County boroughs	137 (490)	137 (166)	63 (57)	32 (37)
Urban districts	366 (370)	134 (139)	77 (69)	42 (42)
Rural districts	252 (176)	92 (57)	63 (31)	60 (37)

The death rates have continuously declined in each area, but the figures supplied by the Registrar-General, the first of their kind, show a striking difference between areas. The rate for London in 1944 was only one-tenth of that in rural districts. In 1944 the rate for London was only one-twenty-third, and that for the rural districts one-fourth, of the 1921 level. A factor of importance is pasteurization of milk. Before 1923 no milk was pasteurized under licence, though in London and a few

larger towns some was "flush" heated, particularly in hot weather to prevent souring. By 1938 over 50% of the milk consumed in county boroughs was pasteurized, and over 98% in London.

Week Ending February 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,307, whooping-cough 1,632, diphtheria 510, measles 1,587, acute pneumonia 1,125, cerebrospinal fever 71, dysentery 406, paratyphoid 4, typhoid 7. One case of smallpox was imported. Deaths from influenza in the great towns numbered 141.

Medical News

A meeting of the Middlesex County Medical Society will be held at the West Middlesex County Hospital, Isleworth, on Tuesday, March 12, at 3.30 p.m.

The next meeting of the Food Group of the Society of Chemical Industry will be held in the rooms of the Chemical Society, Burlington House, Piccadilly, W., on Wednesday, March 13, at 6.30 p.m., when papers will be read on phosphatase activity as an index of heat damage in cereals, on the absorption of aneurin (vitamin B₁) on sand, and on the effect of tinplate and of lacquered surfaces on the oxidative deterioration of butterfat. Members may introduce friends personally.

The following radiological meetings will be held in London this month. Thursday, March 14, 8 p.m., British Institute of Radiology (32, Welbeck Street, W.), presidential address by Dr. L. H. Clark, "Hospital Physics"; Friday, March 15, 2.30 p.m., Therapy Section Meeting of Faculty of Radiologists at Royal College of Surgeons of England (Lincoln's Inn Fields, W.C.), discussion on "Orbital Tumours" to be opened by Mr. Harvey Jackson, Mr. H. B. Stallard, and Dr. John Raban; Friday, March 15, 8 p.m., meeting of Radiology Section of Royal Society of Medicine at 1, Wimpole Street, W., paper by Prof. A. Lacassagne, of Paris. The annual meeting of the Faculty of Radiologists will be held at Glasgow on Friday and Saturday, June 28 and 29.

The annual general meeting of the Institute of Almoners will be held at 6 p.m. on Friday, March 15, in the Great Hall of B.M.A. House, Tavistock Square, when Sir Ernest Rock Carling, F.R.C.S., will give an address.

The Tuberculosis Association will meet at 26, Portland Place, London, W., on Friday, March 15. The Council meeting at 3.30 p.m. is to be followed by an ordinary meeting at 5 p.m., when papers on design and equipment of the modern chest clinic and of the modern sanatorium will be read. At 8 p.m. Dr. Philip Ellman and F. Ridehalgh will open a discussion on "The Changing Chest Clinic." On March 16 a special meeting at the Essex County Hospital at Black Notley begins at noon with demonstrations in the wards. At 2 p.m. in the King Edward VII Memorial Hall the speakers will be Dr. W. A. Bullough, Dr. Raymond Cohen, Mr. R. Reid, Dr. Franklin G. Wood, and Dr. M. C. Wilkinson.

Dr. C. P. Blacker will speak on "Galton's Outlook on Religion" at a members' meeting of the Eugenics Society to be held on March 19, at 5.30 p.m., at the rooms of the Royal Society, Burlington House, W.1.

Dr. Kenneth Tallerman will lecture on some medical conditions in childhood to the Association of Austrian Doctors in Great Britain on Friday, March 15, at 7.30 p.m. at 69, Greencroft Gardens, N.W. (near Finchley Road station).

The North-West London Branch of the English New Education Fellowship announces a public lecture on "Penicillin: Its History, Present Uses, and Possibilities," by Mr. A. L. Bacharach, M.A., F.R.I.C., on Wednesday, March 27, at 7.45 p.m. in the Hall, Hendon County School, Golders Rise, Hendon, N.W.4. Chairman: Dr. A. F. Adamson, medical officer of health, Hendon. The meeting is open to all members of the public.

A group of settlements in Bethnal Green is running a series of short vacation courses under the title "Discover Your Neighbour," for professional workers in training (including doctors, lawyers, teachers, and probation officers). The object is to provide a broad general picture of the social field with only a restricted part of which the professional person will be directly concerned; and to emphasize the need for an understanding of the human factor involved. It consists mainly of practical assignments (in shops, factories, and so forth) bringing students into everyday contact with the life of the neighbourhood, of discussions and tutorials to supplement particular observations. The next course runs from March 27 to April 17. Further information is available from the Vice-Head, Oxford House, Mape Street, Bethnal Green, E.2.

The N.W. London Blood Supply Depot, Slough, and N.E. London Blood Supply Depot, Luton, are amalgamating, and from March 11 will operate as the North London Blood Supply Depot, in the charge of Dr. J. V. Shone, at Shaftesbury Avenue, East Barnet, Herts (tel.: Barnet 0165). Dr. J. V. Shone has been in joint charge of the N.W. and N.E. London Blood Supply Depots for some months.

The Royal Medical Foundation of Epsom College announces that the Conjoint Committee will award in May next a "Cheyne" annuity of £35 per annum to the spinster daughter of a medical man. Candidates must be Protestants, fully 65 years of age, whose income does not exceed £120 per annum irrespective of help from the Royal Medical Benevolent Fund. There is also vacant a "Dr. T. W. Thomas" annuity of at least £25 for a spinster daughter of a medical man in necessitous circumstances who has attained the age of 40 years. Forms of application may be obtained from the secretary, at the Secretary's Office, Epsom College, Surrey, and must be completed and returned by April 18.

Six Norwegian scientists are visiting this country under the auspices of the British Council to meet British scientists and visit universities, scientific institutions, and factories. The leader of the party is Dr. G. H. Monrad-Krohn, professor of medicine, and physician in charge of the Neurological University Clinic, Oslo.

An urgent appeal to join the Civil Nursing Reserve as emergency members is made by the Department of Health for Scotland in a letter on behalf of the Secretary of State addressed to people who have ceased to be active nurses because of marriage or other reasons. Emergency members called on for service will receive salary and emoluments at the rates currently applicable to members of the Civil Nursing Reserve; they will also be provided with uniforms. Volunteers may enrol for either whole- or part-time service, and will be accepted for service in their own district if they cannot volunteer for mobile service. Inquiries should be addressed to the Chief Nursing Officer, Department of Health for Scotland, St. Andrew's House, Edinburgh.

Sir Heneage Ogilvie, K.B.E., M.Ch., F.R.C.S., has been appointed editor of the *Practitioner* in succession to Dr. Alan Moncrieff, F.R.C.P., who has resigned on his appointment to the Nuffield chair of child health in the University of London. Sir H. Ogilvie, who received his knighthood in the New Year Honours list for distinguished services during the war, is surgeon to Guy's Hospital, a Vice-President of the Royal College of Surgeons, honorary major-general and consultant surgeon to the British Army. Prof. Moncrieff has been senior editor of the *Practitioner* since 1943, when he succeeded the late Sir Humphry Rolleston, Bt. Dr. William A. R. Thomson, who joined the *Practitioner* in 1944, will continue as associate editor.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumshough Gardens, Edinburgh.

ANY QUESTIONS?

Biochemistry of Epilepsy

Q.—Is there any literature on the biochemistry of epilepsy, particularly with regard to the serum calcium, phosphorus, and phosphatase? Can hyperinsulinism cause epileptic fits?

A.—The idea that some biochemical abnormality may underlie epilepsy is at first sight so plausible that exhaustive investigations have been carried out on epileptics. We know that the liability to attacks may be influenced by changes in the acid-base equilibrium of the body, and by variations in the blood sugar, and by alterations in water concentration in the tissues. But this does not mean that any of these is the primary abnormality, and no constant biochemical change has ever been found in epileptics. Hyperinsulinism may certainly cause epileptic attacks, but spontaneous hyperinsulinism is a condition nosologically distinct from epilepsy. A full account of biochemical investigations on epileptics will be found in "Epilepsy," by W. G. Lennox and S. Cobb (*Medicine*, 1928; 7, 105). It is there stated that blood calcium, serum phosphorus, and blood phosphatase

have all been found to be normal in epileptics by various investigators. Softening of the bones has not, so far as I know, been observed in epileptics. To be significant the observations would need to be compared with a control made on a group of non-epileptics of similar ages living in similar conditions.

Transmission of Syphilis

Q—*A man contracted syphilis at 19 was apparently cured married and had one child. The child was born when the father was 31 and is now quite well aged 7. When the father was 33 he began to get symptoms which have since proved to be those of G.P.I. There is no question of the man having contracted syphilis after his child was born. His wife is quite well and her W.R. is negative. Is there any possibility of the child being able to pass on syphilis to any children she may have?*

A—There is no fear of the girl conveying syphilis to any children she may have. Presumably the father's syphilis dated back some eleven years before he was married, thus, together with the fact that he apparently had a good deal of treatment, would guarantee that he would not pass the disease on to his wife. Her negative serum reaction is another piece of evidence that she did not contract syphilis. It is now almost universally held that a syphilitic father cannot beget a congenital syphilitic child without infecting the mother. For confirmation the child's blood might be submitted to Wassermann and/or Kahn tests, but this does not seem necessary.

Sleepiness and Obesity

Q—*A woman aged 40 with two children has suffered for the past twelve months with attacks of sleepiness (which do not resemble narcolepsy). She is obese. Is this likely to be due to an endocrine dysfunction? What line of treatment should be adopted?*

A—Pathological sleep with obesity suggests a disturbance of the pituitary-hypothalamic mechanism. Pituitary dysfunction causing a decrease in activity of the gland will result in hypersomnia and obesity, well illustrated in Dickens's Fat Boy. This decreased activity may be due to one of several causes, one of which is adenoma of the inactive chromophobe cells of the pituitary. Tumours and other lesions in the region of the third ventricle of the brain will also give these symptoms, and they are perhaps more likely to be well marked in the absence of other symptoms when due to such a lesion than when due to a disorder of the pituitary gland itself. It is therefore desirable to try to discover by neurological and radiological examination whether the endocrine dysfunction responsible for the symptoms has a local and gross cause. If it has not, medical treatment may be tried. Although direct replacement therapy might be expected to give excellent results, in most cases this is not so, and symptomatic treatment with amphetamine (benzedrine) and thyroid will probably be the most beneficial.

Oily Seborrhoea

Q—*Can you please tell me the treatment for a greasy scalp?*

A—Oily seborrhoea is more difficult to remedy than the dry variety, in which some form of greasy application can be used as a substitute for a natural deficiency. In oily seborrhoea the following hair lotion may be tried: tannic acid 10 gr (0.65 g), resorcin 4 gr (0.25 g), spirit of rosemary or industrial spirit 1 dr (3.5 ml), and water to 1 oz (28.4 ml). This application is unsuitable for white or grey hair, because of its staining qualities. It is significant that in women a permanent wave usually checks the greasy (oily) state for some months.

Duties of a House-governor

Q—*What is the office of "house governor" in a general hospital? Who or what does he govern? What are the usual qualifications required of such a person? What are his duties and responsibilities?*

A—The chief administrative officer of a voluntary hospital is variously described as house governor, secretary superintendent, or secretary, and he corresponds in business life to a general manager. All matters concerning the hospital reach the chief executive committee through him, and all instructions given by that committee should be communicated to various departments by him. He is the committee's chief executive officer. He is usually required to have had considerable experience in hospital administration, and generally holds membership of the Institute of Hospital Administrators. The chief executive officer is not only the channel through which approach to the committee of management is made by anyone, medical or lay, in matters of administrative importance, but he is also responsible for the guidance of the committee in matters such as building, construction and finance.

Training is usually through the medium of the junior posts in hospital service, but lately King Edward's Hospital Fund for London has inaugurated a small number of bursaries. Examinations are conducted by the Institute of Hospital Administrators and include, among other subjects, law, secretarial duties, accountancy, and a knowledge of purchasing supplies and of hospital construction. At present, recommendations have been published by the British Hospitals Association for a scale of salaries which may be used at the discretion of individual hospitals.

Aphthous Ulceration of Mouth

Q—*An edentulous woman has aphthous ulcers, which recur in crops. She has been treated with large doses of vitamins B and C, and local antiseptics to her mouth, the most successful of which is 1% gentian violet (aqueous). Her digestion is poor. Is any other treatment indicated?*

A—Aphthous ulceration of the mouth can be an extremely intractable condition, and several suggestions for treatment have appeared in these columns (cf. *Journal*, April 22, 1944, p. 579). The following additional suggestions are made in the present case. Penicillin lozenges sometimes help by clearing up secondary infection. The association of aphthous stomatitis with sprue and diarrhoea disturbances suggests that there is sometimes a nutritional deficiency in these cases, and recent work indicates that the substance lacking may be related to, or identical with, the active principle of liver extract. It would therefore be a justifiable expedient to try the effect on this lady of a course of intramuscular injections of liver extract—say 4 ml of a crude extract on alternate days.

Removing Wax from the Ears

Q—*For removing wax from the ears glycerin and carbolic drops are rather tedious in use, is there a better solvent which works in a few minutes and which can be used with safety as often as required?*

A—A solvent at once harmless and always readily available is liquid paraffin, which can be used just as suggested. An alternative is ether soap.

Treatment of Blushing

Q—*Can you suggest any treatment for blushing?*

A—Apart from a possible autonomic instability, blushing is most commonly the result of psychological causes. Blushing obviously implies shame and inferiority, the cause of this may be entirely repressed and unknown. The child who has a sense of superiority and receives a bad snub may develop a "conditioned reflex," so that whenever he is wanting to shine he is immediately seized with the inferiority complex and blushes. An interesting feature about neurotic blushing is that we find that it is not merely the blush of shame but the flush of anger, and it is as much due to a repressed aggression as a repressed feeling of shame. To cure it radically the discovery of the causes with the release of the emotions is necessary. In some cases atropine is of value, not only in affecting the end results, but because in many cases a vicious circle has been set up: the patient does not blush because he feels shame, even unconsciously, but feels shame that he blushes. To get rid of the end result of the blushing may break this vicious circle, no longer fearing the blushing, he regains confidence, and no longer blushes.

Thoracoplasty

Q—*What is the present position of thoracoplasty in the treatment of pulmonary tuberculosis?*

A—Thoracoplasty is at present occupying an increasingly important position in the treatment of pulmonary tuberculosis. This is largely due to advances in operative technique and to improved after care. The modern operation of carefully graded rib resection, combined with apicectomy, is much less severe than the older Sauerbruch operation or its modifications, it has a lower mortality, can be used in the treatment of earlier disease, and closes tuberculous cavities more efficiently and certainly. Many authorities now recommend primary thoracoplasty as the treatment of choice for patients with unilateral, localized, grossly cavitated apical disease. Improvements in after-care have done much to reduce post-operative deformity and render the operation a much less mutilating procedure than it used to be. As a full account of the indications for thoracoplasty cannot be given here, the inquirer is referred to a series of papers by Price Thomas which deal with the theory, technique, and results of the modern operation (*Brit J Tuberc.*, 1942, 36, 4 and 109, 1943, 37, 2).

Renal Function Tests

Q—*Fishberg suggests that the "water-concentration test" is the most delicate of all tests for renal function. As it is so simple, the question arises whether it shows impairment the more laborious tests such as the urea clearance should also be done. What are the accepted renal function tests to-day?*

A—Reference to A. M. Fishberg's *Hypertension and Nephritis* (1939) does not make it clear what the questioner means by the "water-concentration test," but the book contains an excellent assessment of many accepted renal function tests, on which the following reply is largely based.

One of the most delicate signs of impairment of renal function is inability to produce a concentrated urine. This is most simply tested by observing the specific gravity of the urine in the first few specimens following a twelve-hour overnight fast: the maximum specific gravity should be 1026 or over, but a figure of 1020 is usually regarded as adequate. Urinary volume must be considered with the concentrating ability, because in some conditions—for example, dehydration—there may be an inadequate blood flow

through the kidneys; functional impairment of the kidney may then be evidenced by a fall in urinary volume with a very high specific gravity. If the specific gravity of the urine can rise to 1020 or over, and the twenty-four-hour volume is 600 ml. or more, then there is no significant impairment of renal function and more elaborate and expensive tests are unnecessary.

If the above criteria are not satisfied, renal function is impaired. The next step then is to determine if the impairment is severe enough to cause retention in the blood of potential urinary constituents. This information is most conveniently given by estimation of the blood urea; it is not given by the urinary volume and maximum specific gravity tests. Van Slyke's urea clearance test is the most popular of the clearance tests. It can detect early impairment of renal function, and is a useful method of following progress. There are many other useful tests of renal function, and the choice is often a matter of personal preference and experience; selection and interpretation must always be made in relation to the clinical condition of the patient.

Disease and Personality Types

Q.—In the "New Statesman and Nation" it was stated that research (apparently American) has established, among other things, that high blood pressure, coronary insufficiency, gastric ulcer, or asthma and hay-fever, are usually associated with specific types of personality, and that the sufferer from coronary disease is likely to be one who has a basic conflict with authority. Can we hear more about this?

A.—It is impossible to answer this question in the space available. A large amount of research work of the type mentioned has been done, the effect of which is to show that patients suffering from various constitutional physical disorders do tend, on the average, to differ from controls in personality make-up. This does not mean that they are exclusively of one type, or that they are to be considered abnormal. These types of personality are frequently differently assessed by different observers, so that the picture of the typical sufferer from, say, gastric ulcer drawn by one expert will differ in material points from that drawn by another. The evidence regarding the incidence of particular types of psychological stress—e.g., that suggesting that coronary subjects have a conflict with authority—is often rather shaky. The commonest fault is that evidence is not given that similar conflicts are not as frequent in sufferers from other diseases.

Storage of Drugs

Q.—Is it safe to use ether and chloroform, ampoules of morphine and of strychnine, and capsules containing barbiturates, after six years' storage?

A.—It is not really possible to give a general reply to this question, as the condition of the drugs will depend generally on the conditions of storage over this period, and in certain cases will depend on the drugs themselves. For example, certain drugs will have kept perfectly if stored in well-closed containers in the dark, and in a dry atmosphere at a moderate temperature. On the other hand, a drug such as digitalis, even if stored under the most ideal conditions, will have lost all its potency long before now, while other drugs will be quite all right even if stored under the most varied conditions for long periods.

Regarding the specific items mentioned, the ampoules of strychnine should be all right, and the capsules containing dry powders of the barbiturates should also be all right, provided they have been kept perfectly dry. To be on the safe side, however, it would be advisable not to use either of the anaesthetics or the ampoules of morphine.

LETTERS, NOTES, ETC.

Delayed Resolution and Pneumonia

Dr. THOMAS ANDERSON (Glasgow) writes: I have been accustomed to read with interest the "Any Questions?" feature of your *Journal*, especially on matters outside my own particular province. I had assumed that the answers were authoritative, and that though differences of opinion might well exist, still, the answer was one expert's point of view based upon authentic experience. The reply on delayed resolution and pneumonia (Feb. 9, p. 225) has, however, undermined my confidence, for it seems to draw some unwarranted conclusions and to contain serious inaccuracies. To begin with, I do not think there is any evidence to support the accuracy of the first two sentences. Lipiodol will enter the area involved in an apparently normal manner. Small pockets of pus have not been an underlying cause in my own cases. After all, empyema now only occurs in some 3 to 4% of cases. Sentence three is somewhat difficult to follow. How can one recognize a condition early when, by its name, it is a late complication? The advice offered in the second part of this sentence is surely unwise, for delayed resolution is non-bacterial, so that a course of sulphonamides or penicillin will be of no avail, since neither of these materials will alter a non-bacterial pathological process. Sentence four is a matter of opinion and, of course, the writer is entitled to hold it. I have not, however, found such measures helpful in a fairly large number of cases. Sentence five is also one with which I cannot quarrel, for it must

depend on clinical judgment of a method of treatment I have not tried. But the really extraordinary sentence is the last. "There is no real evidence." Is there any evidence at all? "If the former is used correctly." What is the correct method of using either drug which prevents delayed resolution? So far as pneumonia in Glasgow is concerned, delay in resolution is now the commonest complication of this disease. Serial x-rays have been studied in my own unit over a number of years and leave no room for doubt that, especially in those over the age of 40, the complication (defined as consolidation clinically and radiologically proved after the 35th day of illness) is exceedingly common. The exact cause can be a matter of discussion, but surely the views expressed in a recent article in the *Lancet* (Anderson, T., and Ferguson, M. S., 1945, 2, 805) cannot just be waved aside? My purpose in writing, however, is not in any sense to push forward opposing views. It is to suggest that the answer given brushes aside as of little importance a problem which is a very serious one, and that it contains inaccuracies on matters of fact.

First Aid for Cresol Burns

Dr. A. E. P. MARTIN (Leeds) writes: In "Any Questions?" on Feb. 2 (p. 191) in advice for first aid for cresol burns it is suggested that only washing with water and covering with sterile cloths is required before dispatch to hospital. If any large area of the body is covered with phenol or cresol (hot or cold) serious liver damage is likely after such treatment. The best treatment I know is washing with a jet of alcohol or acetone until the skin appears no longer white but slightly reddened. If this is done within a few minutes or so nothing more need be done with cold phenol or cresol. I suggest that all works dealing with these substances should have a large alcohol wash-bottle ready as an essential part of first-aid equipment.

Plastic Surgery in Yugoslavia

At the request of the Yugoslav Government U.N.R.R.A. arranged a preliminary visit of Sir Harold Gillies to that country last summer. Following his recommendations, arrangements were made by U.N.R.R.A. for a team of British plastic surgeons to visit Belgrade to demonstrate to the Yugoslav surgeons the latest methods in plastic repair of the mutilations and injuries suffered by the Yugoslav people in the war. The authorities placed at their disposal the most modern hospital in Belgrade of 120 beds, which has, fortunately, escaped damage during the heavy bombing of the city. Already a number of operations have been carried out under the direction of Mr. James Cuthbert and Dr. Robert Shackleton. The work of the British team has been highly appreciated and the results have been seen by Marshal Tito, who recently visited the hospital with the British Ambassador. After expressing his gratitude, the Marshal remarked: "I have never seen this most important work before." Such co-operation in the human art of healing should do much to cement the bonds existing between the two countries. It is understood that the Yugoslav authorities have asked U.N.R.R.A. if arrangements could be made for the British team to extend their stay.

Auscultatory Percussion

THREE FINAL-YEAR STUDENTS of Edinburgh University write: With reference to Mr. L. R. C. Agnew's note (Jan. 19, p. 116) we suspect that the results obtained are to a certain extent subjectively influenced. A simple experiment will prove this conclusively. If the reader will place his stethoscope on the patient's sternum, as recommended by Mr. Agnew, and scrape with the forefinger towards the chest-piece with his eyes shut he will probably find a marked change in intensity of the sound produced on reaching any point lying on a circle at a certain distance from the chest-piece. If he scrapes hard enough he may even detect a second circle at a similar distance beyond the first. Both these circles will clearly be seen to have no relation to the cardiac outline. A similar experiment carried out on the thigh will demonstrate these same changes in intensity. By varying the intensity of the scrape it will be found possible to vary the distance from the chest-piece at which the change occurs. We therefore suggest that the practitioner unconsciously alters the intensity of the scrape to fit in with his preconceived notions. We would like to add, however, that it is possible in at least some subjects to demarcate the lower border of the liver by auscultatory percussion using the blind method as here: in addition to a change of intensity, there is a change of quality—namely, from tympanicity to dullness.

"Coccygodynia" or "Prostatalgia"?

"ANOTHER VICTIM" writes: As a sufferer myself, I think I can help Dr. T. Astley Cooper (Feb. 2, p. 192) to solve his problem. But first I would correct the diagnosis, which I am sure is inaccurate. My own diagnosis would be "prostatalgia" if the term were admissible. In my experience the pain almost invariably has followed sexual intercourse. Chilling of the perineum may cause it. There feels to be something of spasm in the pain, which may be agonizing. Relief comes, in any case, after a period, but is immensely expedited by applying heat to the perineum. The passage of flatus is, I believe, irrelevant. Modesty compels me to request anonymity.

LONDON SATURDAY MARCH 16 1946

PENICILLIN IN SUBACUTE BACTERIAL ENDOCARDITIS

REPORT TO THE MEDICAL RESEARCH COUNCIL ON 147 PATIENTS TREATED IN 14 CENTRES APPOINTED BY THE PENICILLIN CLINICAL TRIALS COMMITTEE

BY

Prof. RONALD V. CHRISTIE, M.D., D.Sc., F.R.C.P.

Secretary of the Committee

Only 18 months ago few patients suffering from bacterial endocarditis had been treated with penicillin in this country, and the results both here and in the U.S.A. were far from encouraging. Early in 1945 reports were received from America which suggested that better results might be obtained with larger doses given for longer periods. An attempt to determine the best system of dosage was clearly indicated, both to save life and to prevent wastage of a valuable drug still in short supply. Since subacute bacterial endocarditis is an uncommon disease, it was decided that this could be best achieved by a co-ordinated effort, and in February, 1945, an announcement was made in this *Journal* of the formation of research centres at Belfast, Bristol, Edinburgh, Leeds, Liverpool, London (St. Mary's, Middlesex, and St. Bartholomew's Hospitals), Manchester, and Sheffield. In April four further centres were formed, in Birmingham, Cardiff, Glasgow, and Newcastle. The response to this announcement can be gauged from the fact that by the end of September, 1945, the treatment of 147 patients had been completed. Since that date many more have been treated, but these will be included in a later report, as a adequate follow-up is essential in assessing the results of the treatment of this disease.

Therapeutic Results

Penicillin was given either by three-hourly injection or by continuous intramuscular infusion. No difference in the therapeutic results could be demonstrated, and opinion on the merits of these two methods is divided. Most are agreed, however, that both methods should be available if the treatment of subacute bacterial endocarditis is to be undertaken.

In the first group to be treated the dose was planned to show the relative importance of duration of treatment and the total amount of penicillin given. An answer to this question is given in Table I, which summarizes the results in 46 patients, all of

TABLE I—Patients receiving a Total of 5 million Units of Penicillin, given in Courses lasting 5, 10, and 20 Days

Dose	Died	Relapsed	"Cured"	Average Follow-up
1 mega unit for 5 days ..	6 (13%)	14 (70%)	0	—
5 mega unit for 10 days	7 (14%)	5 (25%)	3 (25%)	217 days
25 mega unit for 20 days	4 (3%)	3 (21%)	7 (50%)	249 "

Figures in brackets in Tables I-IV represent number of patients in whom stage was only approximately as stated.

whom received 5 mega (million) units of penicillin but over different periods of time: 20 patients were given 1 mega unit a day for five days, and all relapsed or died; 12 received 0.5 mega unit a day for 10 days, and of these 3 were apparently cured; 14 were given 0.25 mega unit a day for 20 days, and of these 7 have remained well. These patients have been under observation for over 6 months, and since relapses, if they occur, most invariably take place within 6 weeks of treatment (Table V) the conclusion appears to be justified that, within these limits of dosage, the duration of treatment is of much greater importance than the total amount of penicillin given: increased dosage is no substitute for prolonged treatment.

The results of treatment in a further series of 66 patients are shown in Table II; all received penicillin for 28 days, but the

TABLE II.—Patients Treated for 28 Days with a Daily Dose of 0.1, 0.25, and 0.5 Mega Unit

Dose	Died	Relapsed	"Cured"	Average Follow-up
0.1 mega unit a day	3 (3%)	5 (11%)	6 (43%)	198 days
0.25 mega unit a day	13 (5%)	4 (3%)	17 (50%)	117 "
0.5 mega unit a day	7 (39%)	0	11 (61%)	114 "

dose was varied, one group receiving 0.1 mega unit a day, another 0.25 mega unit a day, and another 0.5 mega unit a day. In the first group 43% recovered, in the second group 50%, and in the third group 61% have remained cured after an average follow-up of 4 months. It should not be forgotten that, no matter how effective penicillin may prove to be in the treatment of this disease, a significant death rate will remain from causes such as heart failure, uraemia, and major emboli. These deaths, many of which occurred during treatment, have little or no bearing on the efficacy of penicillin, and when this is borne in mind the therapeutic results shown in Table II are all the more remarkable—11 out of 18 patients receiving 0.5 mega unit a day for 28 days have remained cured. In only 1 of the 7 patients who died was there any evidence that the penicillin had failed to control the septicaemia, and the infecting organism in this case was more than 32 times as resistant to penicillin as the standard Oxford staphylococcus. For previously untreated patients 0.5 mega unit a day for 28 days seems to be a most satisfactory system of dosage.

Another small group of 12 patients received 0.5 mega unit a day for 21 days; of these, 1 died, 2 relapsed, and 9 have remained well after an average follow-up of 244 days.

Lastly, there were 11 patients who received a system of dosage which did not fall into any of the categories described above: 5 of these died, 1 relapsed, and 5 have remained well for an average period of 172 days.

Effect of Inadequate Treatment

It is of considerable practical importance to know whether inadequate treatment, as well as wasting time and penicillin, is prejudicial to later success. The results of treatment in patients who had already received a short course of penicillin are given in Table III. A comparison of this table with Tables I and II

TABLE III—Patients Previously Treated with a Short Course of Penicillin, of 5-10 Days' Duration

Dose	Died	Relapsed	"Cured"	Average Follow-up
1 mega unit for 5 days ..	0	1	0	—
0.5 mega unit for 10 days	0	0	2	220 days
0.1 mega unit for 28 days	0	2	1	232 "
0.25 mega unit for 20 days	4 (3%)	1 (1%)	3 (3%)	260 "
0.25 mega unit for 28 days	0	3 (2%)	6 (4%)	162 "
0.5 mega unit for 28 days	0	0	3	175 "
Total ..	4 (15%)	7 (27%)	15 (58%)	

does not suggest that previous treatment with a short course is prejudicial to later success in the patients who survive.

The results of treatment in patients who had already received a long course of penicillin are given in Table IV. A comparison

TABLE IV.—Patients Previously Treated with a Course of Penicillin of 20–28 Days' Duration

Dose	Died	Relapsed	"Cured"	Average Follow-up
1 mega unit for 5 days	0	1	0	—
0.5 mega unit for 10 days	0	1	0	—
0.1 mega unit for 28 days	0	0	1 (1)	214 days

of this table with Tables I and II shows that if a patient does not respond to a long course of treatment he is less likely to respond to a second course. There are two possible explanations. Lack of response to the first course may indicate natural resistance to penicillin therapy, so that this forms a selected group of resistant cases. Alternatively, the explanation may be that an ineffectual course of treatment may increase the resistance to penicillin.

Repeated estimations of the resistance of the infecting organisms to penicillin were made in this series, but no convincing evidence of changes in sensitivity was found. Sixteen patients received more than one long course (20 days or more) of treatment, and in only two of these was there any evidence of a change in sensitivity; in both there was a threefold increase in resistance to penicillin as measured by the ordinary dilution methods. Clinical evidence bearing on the question of acquired resistance to penicillin is also meagre, and is confined to two small groups. The first group was of 7 patients in whom septicaemia was uncontrolled during treatment; in 2 it was uncontrolled from the start, but in the other 5 the infection had been previously controlled by a similar or smaller daily dose of penicillin, suggesting that resistance to penicillin had increased; in all of these 5 patients the first course, which seemed at the time to be effective, involved a daily dose of only 0.1 to 0.25 mega unit. In the second group there were 5 patients who relapsed after a second long course of penicillin; in all, the dosage of penicillin was greater in the second than in the first course, and yet the interval before relapse was decreased rather than increased.

This evidence is, to say the least, not incompatible with acquired resistance to penicillin. Delay in controlling the infection also exposes the patient to the many dangerous complications of this disease, and it is therefore safer, from the patient's point of view, to assume that inadequate treatment is prejudicial to later success.

Relapses

Short courses of treatment, of 10 days or less, are usually followed by relapse within a few days. Even after long courses most relapses occur within 30 days of cessation of treatment, and relapse after 50 days is extremely rare (Table V). The con-

TABLE V.—Relapses after Treatment

Interval between Treatment and Relapse	Relapse After Treatment Lasting 20 Days or More	Relapse After Treatment Lasting 10 Days or Less
0–10 days	14	17
11–20 "	7	3
21–30 "	6	2
31–40 "	0	1
41–50 "	2	0
51–60 "	0	1
Over 60 "	1 (130 days)	

clusions drawn from Tables I–IV, in which the period of follow-up varied from 107 to 260 days, are therefore not unreasonable. There is still, of course, the chance of reinfection, but this was proved in only one patient of this series; this patient relapsed, and *Streptococcus faecalis* was recovered from the blood 161 days after apparent cure from an infection with *Str. viridans*.

The treatment of relapses presents a special and often difficult problem. Of 16 patients who relapsed after a course of penicillin which lasted longer than 20 days, all but 4 relapsed or died after a second course which was either more prolonged

or of higher dosage than the first. Four patients have received more than two long courses of penicillin, but only one of these has finally responded: she relapsed after 0.5 mega unit for 10 days, again after 0.1 mega unit for 28 days, and again after 0.5 mega unit for 28 days, but has now remained well for 60 days after a fourth course of 0.5 mega unit a day for 42 days. It is this system of dosage—0.5 mega unit a day for 6 or 8 weeks—that we propose usually to adopt in patients who have relapsed.

The Infecting Organism

Of the 147 patients included in this series 146 were infected with streptococci and one with a strain of *Haemophilus influenzae* which was almost completely resistant to penicillin. Of the streptococci 136 are described as *Str. viridans*, 8 as a non-haemolytic streptococcus, 1 as an anaerobic streptococcus, and 1 as a micro-aerophilic streptococcus. The sensitivity to penicillin was measured by the ordinary dilution methods and compared with the standard Oxford staphylococcus. To facilitate tabulation this has been expressed as a coefficient of resistance, and it is clear from Table VI that there is a surprising

TABLE VI.—A Comparison of the Results of Treatment with the Sensitivity of the Organism to Penicillin. (Resistance is expressed as a multiple of the resistance of the standard Oxford staphylococcus.) None of these patients had previously been given a long course of treatment

Dose		Coefficient of Resistance to Penicillin				
		1 or Less	2	3–5	8–10	32–64
0.1 mega unit a day for 28 days	Died	1	2			
	Relapsed	6	1			
	Cured	6			1	
0.25 mega unit a day for 20 days	Died	1		2		
	Relapsed	4				
	Cured	7	1	1		
0.25 mega unit a day for 28 days	Died	6	2	2		
	Relapsed	3	1	1		
	Cured	14	3	2	1	
0.5 mega unit a day for 20 days	Died				1	
	Relapsed		1	1		
	Cured	4	2	1		1
0.5 mega unit a day for 28 days	Died	3	1			2
	Relapsed					
	Cured	8	3	2	1	
Total	Died	11	5	4	1	2
	Relapsed	13	3	2		
	Cured	39	9	6	3	1

lack of correlation between this coefficient and the results of treatment. There were 16 patients infected with comparatively insensitive streptococci having a coefficient of resistance between 3 and 10; 5 of these have died, 9 have been apparently cured, and only 2 have relapsed. These results compare favourably with those in patients infected with more sensitive organisms. There were three patients infected with streptococci more than 32 times as resistant as the Oxford staphylococcus, and this degree of insensitivity may be of therapeutic significance. One of these three was cured after receiving 0.5 mega unit a day for 21 days, but in the other two septicaemia remained uncontrolled while they were receiving 0.5 mega unit a day, and both ultimately died. A fourth patient was infected with an extremely resistant strain of *H. influenzae*, and he relapsed 6 days after receiving 0.5 mega unit a day for 23 days.

These results suggest that the resistance of the organism to penicillin as measured by ordinary titration methods is of no clinical significance within a wide range. Only when the organism was more than 10 times as resistant as the Oxford staphylococcus did this measurement appear to be of therapeutic and prognostic importance. This unexpected result may only reflect some inherent inaccuracy in the methods employed in measuring sensitivity, but this does not affect its clinical importance, since these methods are in general use.

Comments

Of the 147 patients treated in this series, 50 have died and 81 have been apparently cured, but it should not be forgotten that the systems of dosage at first used were inadequate. Of the remaining 16 patients, some are still under treatment and in a few treatment has been discontinued for one reason or another.

This report is concerned only with evidence which has a bearing on the treatment of subacute bacterial endocarditis. It

is expected that a more complete analysis of these and other patients treated within the scope of this investigation will be made at a later date

Summary

The results here reported provide further evidence of the therapeutic value of penicillin in subacute bacterial endocarditis

If the administration of penicillin is continued for 10 days or more almost any system of dosage will occasionally produce excellent results. Relapse is, however, more likely to occur if treatment is not both prolonged and intensive

From the evidence available it is safer to assume that inadequate treatment is prejudicial to later success

In previously untreated patients 0.5 m.m.g. unit a day for 28 days has given better results than any other system of dosage employed

The resistance of the infecting organisms as measured by ordinary titration methods appeared to be of no clinical importance within a wide range. Only when the organism was more than 10 times as resistant as the standard test staphylococcus did this measurement appear to be of therapeutic and prognostic significance

This report is submitted on behalf of a large number of workers who have taken part in this investigation in the fourteen research centres appointed by the Penicillin Clinical Trials Committee.

TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS BY PENICILLIN PRELIMINARY REPORT ON 18 CASES

Research Assistant, Bland-Sutton Institute of Pathology

In February, 1945, we were invited by the Medical Research Council to form one of the centres for investigating the value of penicillin for the treatment of subacute bacterial endocarditis. Since February we have treated 18 cases. All our patients have had penicillin with no heparin, and each case has been given 480,000 units daily by intramuscular injections—60,000 units every three hours, night and day. In the first four months this dosage was continued for 21 days—total, 10 million units—and in every case the blood was rendered sterile almost at once, and the temperature usually settled down within a few days of starting treatment. Two cases relapsed, necessitating a further course of penicillin, so it was decided at the beginning of June to give a course of 28 days instead of 21—total, 13.5 million units—as suggested at a meeting of the Endocarditis Research Committee. Since this plan was adopted we have had no more relapses.

In all our cases streptococci of the *viridans* type had been obtained from the blood, and treatment began only after bacteraemia had been confirmed by positive blood cultures. The only therapeutic measures adopted besides the penicillin were iron or liver preparations for the anaemia and in two cases blood transfusion, vitamin C, and, in one instance, sodium salicylate, antiphlogistine for the relief of localized pain, and mersalyl and digitalis for such cases as showed evidence of congestive failure.

Of these 18 patients four have died, but of these four only one can be considered a failure to respond to penicillin. No. 256 died from cerebral embolism two days after penicillin injections were begun; No. 342 died as a result of a rupture of one of the cusps of the aortic valve; No. 363 died from haemorrhage from enlarged vessels in the oesophagus, which were caused by cirrhosis hepatis; No. 361 failed to show any response to penicillin, and died from pulmonary infarction.

Of the remaining 14 cases two have manifested signs of congestive heart failure. One of these was one of the two cases which relapsed after the 21-days course of penicillin; it has responded well to rest and mersalyl, and now shows no signs of congestive failure. The other case shows early signs of con-

gestive failure, but has refused to come into hospital for further treatment. This patient is still free from infection of the blood. During the course of treatment with penicillin in this case the haemoglobin level fell to 18% as a result of haematemesis.

Thirteen patients have remained free from infection, and have left hospital and are apparently well. One is still in hospital. He has completed his course of penicillin, and shows negative blood cultures but has not yet got a sufficiently stable cardiac mechanism to warrant a claim of uninterrupted convalescence.

No. of Days Treated	No. of Cases	No. Died	No. Relapsed and Re-treated for a further 28 Days	Days Free from Recurrence					
				30-100	100-150	150-200	200-250	250-300	Over 300
21	9	1*	2	3	1	3	1	4	2
28	11†	3							

* This was No. 256, who died on the second day of the course
† Including the two which failed on the 21-days course

Case Summaries

Case 245—Female aged 12. Admitted 23/1/45. After tooth extraction, two weeks previously, had felt unwell, anorexia, fever, sweats, temperature 103°, pulse 120, apical systolic murmur; haemoglobin (Hb) 83%, basal sedimentation rate (B.S.R.) 20 mm/hr. Treated as rheumatic carditis up to 16/2/45, when temperature started swinging again with profuse sweats; two blood cultures positive 23/2/45: Began course of penicillin. Temperature normal, only slight sweats, blood culture negative. 1/3/45: Osler's nodes on fingers, scanty red cells in urine. 11/3/45: Central abdominal pain, temperature 102°, pulse 140; subsided in 3 days; probably small mesenteric embolus. 16/3/45: Penicillin discontinued 5/4/45. Started to get up 30/5/45: Hb 112%; B.S.R. 5 mm/hr. a few red cells in urine. 1/6/45: Discharged to convalescent home. Has been seen on several occasions since then. Remained fit, now back at school.

Case 249—Male aged 29. Admitted 23/2/45. Known congenital heart since age of 2, rheumatic fever at age of 13. Seven months' history of malaise, lassitude, pain in the chest, sweating, swollen ankles, in the same period lost 3 st. (19 kg) in weight. Clubbing of fingers, spleen palpable; to-and-fro murmurs, maximal in third and fourth interspaces 1/2 in. (1.3 cm) from sternum; basal crepitations, blood culture positive on two occasions, moderate red cells in urine, Hb 70%, B.S.R. 40 mm/hr. 25/2/45: Started penicillin 28/2/45. Pain in right side of chest; small pulmonary infarct. Blood culture negative 2/3/45. Temperature normal. 8/3/45: Marked improvement, appetite good, still occasional night sweats. 13/3/45: Penicillin discontinued. 19/3/45: Positive blood culture. One tooth removed under general anaesthesia; covered by 48 hours' penicillin, 60,000 units three-hourly. Culture of roots revealed *Str. viridans*. Remaining teeth removed in four sessions, covered by penicillin 13/6/45: Discharged. Has been seen on many occasions since, the last on 2/11/45. Now back at work as a salesman; 2 st. (12.7 kg) increase in weight; heart unchanged; slight dyspnoea on effort; Hb 106%; B.S.R. 5 mm/hr.

Case 273—Female aged 26. Admitted 16/3/45. Gave a history of rheumatic fever at age of 7. She had suffered from mild cerebral embolism six weeks before admission and had a swinging temperature, with red cells in urine, aphasia, and oedema of ankles. Cafe-au-lait colour, extremely pale. Aortic and mitral lesions; nominal aphasia. Hb 36%; B.S.R. 32 mm/hr; positive blood culture 21/3/45: Started course of penicillin. 26/3/45: No response to iron or liver preparations; 3 pints (1.7 litres) blood transfusion. Occult blood strongly positive. 5/4/45: Haematemesis—30 oz. (0.85 litre), necessitating further transfusion. Hb only 18%. 7/4/45: Small haematemesis. Patient collapsed; pulse irregular, 3 pints concentrated red cells given. Still profuse red cells in urine. 12/4/45: Occult blood still positive. 13/4/45: Discontinued penicillin 17/4/45: Hb 46%; macroscopic haematuria. Heart unchanged; spleen palpable; rales at both bases; profuse red cells in urine. 25/4/45: Frank haematuria; blood cultures remained negative; Hb 52%; B.S.R. 30 mm/hr. 22/6/45: Discharged to convalescent home. Has been seen as an out-patient from time to time, remained well until recently, when some oedema of the ankles developed, for which she has refused treatment. Hb 82%; B.S.R. 8 mm/hr.

Case 289—Female aged 21. Admitted 14/4/45. Two months' history of oedema of ankles and lassitude. Rheumatic fever at age of 8. Night sweats; pain in left lower chest. Very pale; rapid pulse; mitral stenosis; spleen palpable; red cells in urine; Hb 63%. B.S.R. 30 mm/hr.; blood cultures positive. 16/4/45: Started penicillin. 18/4/45: Temperature normal. 9/5/45: Discontinued

penicillin. 11/6/45: Getting up. Hb 94%; scanty red cells in urine; remaining afebrile; blood cultures negative. 18/6/45: Evening temperature 99-100° for several days; blood culture positive on two occasions; tip of spleen palpable. 26/6/45: Further course of penicillin started. 17/7/45: Penicillin discontinued—total 23 million units. 30/7/45: Remained afebrile, with negative blood cultures. 14/8/45: Discharged to convalescent home; Hb 98%; B.S.R. 15 mm./hr. 8/10/45: Readmitted to hospital for treatment of congestive failure. 14/11/45: Good response to treatment. 2/12/45: Discharged. No evidence of heart failure.

Case 293.—Female aged 46. Admitted 14/7/45. Goitre removed at age of 20. Pain in back and legs; occasional sweats. Mitral systolic murmur; petechial spots on hands; café-au-lait colour. Hb 62%; B.S.R. 22 mm./hr.; red cells in urine; positive blood cultures. 19/4/45: Started penicillin. 23/4/45: Temperature normal; appetite improved. 9/5/45: Discontinued penicillin. Still red cells in urine; Osler's node on right hand. 6/7/45: Discharged to convalescent home. 2/11/45: Seen as out-patient; Hb 104%; B.S.R. 3 mm./hr. Doing her own housework with no ill effects.

Case 295.—Male aged 30. Admitted 20/4/45. Rheumatic fever at age of 9. Four weeks' history of pain in left ankle; 10 days acutely ill—fever, rigors, low delirium, confused, irrational, with slow slurred speech. Apical systolic murmur; Hb 90%; B.S.R. 25 mm./hr.; red cells in urine; positive blood culture. 21/4/45: Cerebral embolus resulting in right hemiplegia and aphasia. 22/4/45: Started penicillin. 27/4/45: Some improvement in facial palsy. 13/5/45: Discontinued penicillin. 25/5/45: Speech improved; some movement possible in limbs; blood cultures negative. 4/6/45: Evening temperature raised; two positive blood cultures. 6/6/45: Evening temperature of 101°; further positive blood culture; second course of penicillin. 11/6/45: Four doubtful teeth removed under general anaesthesia. 14/6/45: Still raised evening temperature. 4/7/45: Discontinued penicillin—total, 23 million units. Blood cultures negative; massage and exercises to paralysed limbs. 24/7/45: Getting up in a chair. 27/8/45: Discharged to convalescent home. Blood cultures negative; afebrile; Hb 93%; B.S.R. 16 mm./hr.; walking with a stick. 2/12/45: Seen as an out-patient; gained 2 st. (12.7 kg.) in weight; heart unchanged; no evidence of failure; Hb 108%; B.S.R. 3 mm./hr.

Case 300.—Female aged 40. Admitted 26/4/45. Rheumatic fever at age of 20. Three months' history of loss of appetite, loss of weight, palpitations, tender spots on fingers. Petechial spots and splinter haemorrhages; aortic and mitral lesions; spleen palpable; red cells in urine; Hb 73%; B.S.R. 35 mm./hr.; several positive blood cultures. 28/4/45: Started penicillin. 11/5/45: Slight evening pyrexia; blood culture negative; splinter haemorrhage; red cells in urine. 19/5/45: Discontinued penicillin. 28/5/45: Pain in right shoulder and right arm. 11/6/45: Raised tender red swelling in palm of left hand; blood culture negative; red cells in the urine. 11/7/45: Dental extraction, covered by three days' penicillin. 23/7/45: Discharged to convalescent home. Seen as out-patient on several occasions—last time 2/11/45. Doing housework, weekly washing, etc. Gain in weight. Heart unchanged; no failure. Hb 74%; B.S.R. 4 mm./hr.

Case 302.—Female aged 27. Admitted 26/4/45. Rheumatic story at age of 10 and 23. Pain in left upper chest, lassitude, wasting, loss of weight; café-au-lait colour; splinter haemorrhage; temperature 102°; aortic regurgitation; Hb 54%; B.S.R. 3 mm./hr.; red cells in urine; positive blood culture. Raised tender swelling in palm of right hand. 1/5/45: Started penicillin. 5/5/45: Two further splinter haemorrhages; afebrile; blood culture negative. 14/5/45: Occasional evening pyrexia; Osler's nodes on fingers; red cells in urine. 22/5/45: Discontinued penicillin. 6/6/45: Remained afebrile; blood cultures negative; red cells in urine. 11/6/45: Osler's nodes. 21/6/45: Splenic infarct. 22/6/45: Painful swelling on dorsum of foot; red cells in urine; blood culture negative. 23/7/45: Discharged to convalescent home. Has been seen from time to time. 30/10/45: Heart unchanged; no failure; Hb 90%; B.S.R. 3 mm./hr. Found to be pregnant since discharge; termination advised and carried out.

Case 340.—Female aged 29. Admitted 25/6/45. Rheumatic fever at age of 13. Pain in chest, loss of appetite, breathlessness, palpitations, rigors; drowsy; café-au-lait tinge; petechial spots over the right forearm and splinter haemorrhages beneath the nails. Aortic and mitral lesions; spleen palpable; red cells in urine; Hb 73%; B.S.R. 31 mm./hr.; blood culture positive. 27/6/45: Started penicillin. 28/6/45: Dramatic improvement. 5/7/45: Spleen not palpable; blood cultures negative. 25/7/45: Discontinued penicillin. 7/8/45: Blood culture negative; no embolism; few red cells in urine. 30/8/45: Discharged home; no red cells in urine; Hb 98%; B.S.R. 23 mm./hr. Seen as an out-patient 2/11/45; doing light housework; no evidence of heart failure; heart unchanged; Hb 104%; B.S.R. 3 mm./hr.

Case 341.—Female aged 42. Admitted 10/7/45. Pain in left loin, general aches and pains, rigors, profuse sweats, oedema of ankles. Five teeth removed 6 weeks before admission. Sallow

complexion; splinter haemorrhages; petechial spots on both forearms; apical systolic murmur; spleen palpable; red cells in urine; Hb 70%; B.S.R. 33 mm./hr.; blood culture positive. Started penicillin 12/7/45: General condition improved, no further rigors. 14/7/45: Further crop of petechial haemorrhages; spleen not palpable; profuse red cells in urine. 22/7/45: Severe pain over frontal and maxillary sinuses; relieved 3 days later when several large clots were discharged. 7/8/45: Penicillin discontinued; blood culture negative. 31/8/45: Dental extraction under penicillin cover, several of the teeth growing *Sir. viridans*. 2/10/45: Discharged to convalescent home. Has been seen on several occasions since. Leading a comparatively normal life. Hb 97%; occasional red cells in urine; heart unchanged; no evidence of failure; B.S.R. 5 mm./hr.

Case 360.—Male aged 36. Admitted 27/8/45. Lassitude for 3 weeks; persistent pyrexia. No rheumatic history. 19 teeth removed 7 weeks previously. Swelling of ankles; night sweats. Systolic murmur inside apex; screening confirmed *maladie de Roger*; spleen palpable; Hb 78%; B.S.R. 17 mm./hr.; scanty red cells in urine; positive blood culture. 30/8/45: Started penicillin; rapid response. 26/9/45: Discontinued penicillin. 28/9/45: Heart unchanged; spleen not palpable; blood culture negative; Hb 84%; B.S.R. 7 mm./hr.; few red cells in the urine. 3/11/45: Discharged to convalescent home. 7/12/45: Seen as an out-patient. Gain in weight; no failure; heart unchanged.

Case 364.—Female aged 22. Admitted 10/10/45. No rheumatic history; one month of malaise and fleeting joint pains. Enlarged spleen; mitral stenosis; swelling of ankles; a few petechial spots; positive blood cultures; a few red cells in urine; temperature 101°; Hb 83%; B.S.R. 26 mm./hr. 13/10/45: Started penicillin; general condition much improved. 20/10/45: Osler's node palpable in index finger; splinter haemorrhages under nails of right hand. 10/11/45: Discontinued penicillin. No further evidence of embolism; spleen not palpable. 23/11/45: Blood culture negative; still red cells in the urine; no change in the heart; no failure. 27/11/45: Getting up. 14/12/45: Dental extraction under cover of penicillin. 20/12/45: Discharged. Hb 99%; B.S.R. 14 mm./hr.; no red cells in the urine.

Case 365.—Male aged 29. Admitted 10/10/45. Pain in left groin, swelling of ankles, rheumatic pains in joints. No definite rheumatic history. Febrile; a few petechial spots; mitral stenosis; Hb 76%; B.S.R. 33 mm./hr.; blood cultures positive; red cells in urine. 12/10/45: Started penicillin. 18/10/45: Has remained afebrile since start of penicillin; appetite improved; blood culture negative. 26/10/45: Faint diastolic murmur at aortic area; blood culture negative. 9/11/45: Discontinued penicillin. 22/11/45: Getting up with no ill effects; no failure; heart unchanged. Massage and exercises before discharge. 14/12/45: Dental extraction under penicillin cover. Blood culture negative; Hb 90%; B.S.R. 14 mm./hr. 20/12/45: Discharged.

Case 366.—Male aged 51. Admitted 5/10/45. Had been unwell since influenza in August; fever, lassitude, anorexia. No rheumatic history. Sallow complexion; splinter haemorrhages; aortic and mitral lesions; positive blood cultures; Hb 73%; B.S.R. 22 mm./hr.; red cells in urine. 8/10/45: Started penicillin. 15/10/45: Temperature normal; "has not felt as well for five years"; blood culture negative. 27/10/45: Dull ache in centre of sternum on inspiration. Spreads to left breast—pulmonary infarct. Later very restless, sweating, dyspnoeic; marked engorgement in neck veins; apex beat further out to left; systolic apical murmur had assumed a harsher quality; oedema of lung bases; liver tender; rapid auricular fibrillation; immediate intravenous digitalization. 28/10/45: Pulse regular at 130/min., definite improvement in general condition; failure subsided. 29/10/45: Pulse normal, though rapid rhythm. 5/11/45: Penicillin discontinued. 13/11/45: Pulse regular, 90/min.; heart smaller; no evidence of failure. 27/11/45: Afebrile; blood cultures remained negative. Hb 75%; B.S.R. 20 mm./hr. 31/12/45: Massage and exercises before discharge.

Case 256.—Female aged 56. Admitted 1/3/45, after having had 2 million units of penicillin in two courses, which did not appear to influence the endocarditis. Six months' history of oedema, dyspnoea, lassitude. Aortic and mitral lesions; pain in left ankle; positive blood culture; red cells in urine; Hb 63%. 3/3/45: Started penicillin. 5/3/45: Fatal cerebral embolism. *Necropsy*: Vegetations in left auricle, mitral and aortic valves; infarcts of kidney and spleen.

Case 342.—Male aged 34. Admitted 16/7/45. Pain in left chest; spots on legs; lassitude, increasing dyspnoea; night sweats; oedema of ankles. Clubbing; pale; spleen palpable; petechial rash on legs; Hb 48%; B.S.R. 30 mm./hr.; red cells in urine; positive blood culture; left pleural effusion. 26/7/45: Started penicillin. 1/8/45: Extreme cardiac asthma with further enlargement of the heart; marked aortic regurgitation; rales in both lungs; increasing pulmonary congestion. 13/8/45: Oedema of lungs less; heart still grossly enlarged; frequent extrasystoles; blood culture negative; red cells in urine; spleen not palpable; Hb 60%; B.S.R. 30 mm./hr. 23/8/45: Discontinued penicillin. 29/8/45: Increasing severity and duration of cardiac asthma. 2/9/45: Further increase in oedema

of lungs in spite of all diuretic measures. 6/9/45: Patient became orthopnoeic and died suddenly. *Necropsy*: Large ulceration through the aortic cusps.

Case 361.—Female aged 21. Admitted 11/8/45. No rheumatic history. Oedema of ankles; lassitude; upper abdominal pain; fever; increasing dyspnoea; pericardiac on abdominal walls. Yellowish skin; aortic and mitral lesions; spleen not palpable; red cells in urine; positive blood culture; Hb 66%; B.S.R. 20 mm./hr. 16/8/45: Started penicillin. 20/8/45: Penicillin does not appear to have affected the temperature at all. Central abdominal pain; tenderness over McBurney's point. Course of sulphacetamide for urinary infection, which cleared up. 8/9/45: Boost doses of penicillin 100,000 units did not influence the high temperature. 12/9/45: Discontinued penicillin. 17/9/45: Remaining febrile; red cells in urine. 27/9/45: Finished course of sulphamezathine for bronchopneumonia. Still some consolidation in the left base; blood cultures positive. 1/10/45: Aspirin 10 gr. (0.65 g.) four-hourly—no effect on temperature. 6/10/45: Pain in left chest and area of consolidation. Died next day. *Necropsy*: Large friable vegetations on mitral and aortic cusps; recent infarct left lower lobe.

Case 363.—Male aged 29. Admitted 3/10/45. Two months' history of loss of appetite, increasing dyspnoea, occasional palpitations, tenderness of fingers. Admitted to military hospital 5 weeks ago after three-pint (1.7 litres) haematemesis. Very pale; splinter haemorrhages; Osler's nodes; spleen palpable; red cells in urine; positive blood cultures; mitral stenosis; Hb 65%; B.S.R. 21 mm./hr.; occult blood positive. 4/10/45: Started penicillin. 7/10/45: Temperature normal; general condition much improved. 8/10/45: Febrile; blood culture negative. 9/10/45: Rigor. 15/10/45: Spleen further enlarged; another crop of tender spots on pulps of fingers. 18/10/45: Haematemesis 30 oz. (0.85 litre) bright red blood; replaced by 2 pints (1.14 litres) packed red cells by drip transfusion. 20/10/45: No signs of failure; abdomen less distended; spleen still palpable, not tender. 24/10/45: Haematemesis of 30 oz. bright red blood. "Pulse 110/min.; not sweating or shocked." This was followed by further haematemesis of 20 oz. (568 ml.) bright red blood, later 15 oz. (426 ml.) and 10 oz. (284 ml.). Became shocked, pale, sweating; pulse 160/min., hardly perceptible. Immediate intravenous drip, packed red cells; improved until pulse came down to 90/min. Two hours later further haematemesis of 32 oz. (0.9 litre). In the next 24 hours vomited another 30 oz. of darker blood. Drip discontinued after 10 pints (5.7 litres). 26/10/45: Marked improvement; no evidence of failure; Hb 75%. 28/10/45: Again became shocked; pain and massive distension in upper abdomen; further drip. 29/10/45: Patient died, not having recovered from final haemorrhage. *Necropsy*: Early coarse cirrhosis of the liver; large patent varicose veins in the oesophagus; 2 pints (1.4 litres) of free blood in the stomach, with a clot representing about 3 pints (1.7 litres) more. Small vegetations on mitral valve, not much larger than rheumatic vegetations.

Bacteriology

Blood Cultures.—As has already been mentioned, streptococci of the *viridans* type were isolated from all cases before treatment was started. Qualitative and quantitative methods were used—that is to say, at least 5 ml. of citrated blood was inoculated into 50 ml. of meat extract peptone broth, and a further 2 ml. was used to make two poured-plate cultures. The latter method proved more useful in that, besides providing an estimate of the numbers of bacteria in the blood stream, it gave positive results on several occasions when the fluid culture showed no growth. In each of the cases described here a positive result was obtained with the first blood culture taken after admission, though on one occasion (Case 273) only the fluid culture gave growth. In two subsequent cultures from this case only one colony per ml. was found, so that the failure of the first plate cultures was presumably due to the small number of organisms in the blood. This case illustrates the small variation in the degree of bacteraemia which we found to be the rule in the six cases in which repeated blood cultures were taken before treatment. There were, however, considerable variations in the number of colonies per ml. from patient to patient. Of 30 plate cultures taken before treatment two were negative, eight had 1 to 6 colonies, five 10 to 20 colonies, nine 28 to 60 colonies, five 100 to 250 colonies, and one (Case 256) had 2,000 colonies per ml. A high bacteraemia seemed to have some prognostic significance in that the patients who subsequently died had colony counts of 50, 60, 100, and 2,000 per ml.

Starting from the second to the sixth day, three to six blood cultures were taken during the course of treatment, and all were negative except in three cases, two of which were the only cases that subsequently relapsed. It would thus appear that a positive

blood culture during the course of penicillin treatment may be an indication that relapse is likely to occur. In Case 249 a positive blood culture was obtained on the day after stopping penicillin treatment, but this was regarded as due to a transient invasion probably from infected teeth, because there were no clinical symptoms of active infection, and since then blood cultures have been consistently negative.

Characters of the Isolated Streptococci.—The streptococcal strains isolated from these cases before treatment all displayed alpha-haemolysis typical of the *Str. viridans* group, with the exception of one strain (Case 342) in which haemolysis was slight and more of the beta type. Of these strains 14, excluding that from Case 342, have been maintained for further study, and preliminary work shows that they can be divided into two main fermentation groups. The first group, comprising six strains, ferment lactose, and in their range of fermentation reactions correspond well with *Str. salivarius*, described by Andrewes and Horder (1906) as the most common type of *Str. viridans* in the mouth and nasopharynx, and of frequent occurrence in subacute bacterial endocarditis. The second group, comprising eight strains, do not ferment lactose and are less readily identified with known strains. Okell and Elliott (1935), however, have found streptococci of the *viridans* type that do not ferment lactose in 11 of 36 strains isolated from cases of subacute bacterial endocarditis and in 11 of 26 isolations in blood cultures from cases of dental sepsis. It would therefore appear likely that our strains of the second group can also be mainly associated with *viridans* strains commonly found in the region of the mouth.

Penicillin Sensitivity.—The streptococci from these cases were tested for penicillin sensitivity by the method described by Selbie, Simon, and McIntosh (1945). In general, and like other strains of *Str. viridans* that we have tested, they were rather more resistant to penicillin than most strains of *Str. pyogenes*. Twelve strains were in the range of being not less than half and not more than twice as sensitive as the Oxford staphylococcus, while four strains were 4 times less sensitive and the strains from Cases 363 and 273 were 4 and 8 times more sensitive than the Oxford staphylococcus. There was no apparent correlation between penicillin sensitivity and the fermentation reactions of the organisms or the results of treatment. In the two cases which relapsed there was no difference in sensitivity between the organisms isolated before and after treatment.

Penicillin Blood Levels.—The dosage of penicillin during treatment was controlled by the estimation of penicillin in the blood serum by the method previously described (Selbie, Simon, and McIntosh, 1945). In general, after the intramuscular injection of 60,000 units of penicillin the blood serum inhibited the growth of the Oxford staphylococcus in a dilution of 1/32 to 1/128 at one-quarter to half an hour, and 1/1 to 1/8 at 3 hours. In Case 363, however, penicillin levels were rather low, and in Case 273 the bacteriostatic dilutions remained high, and were 1/32 and 1/64 even at the end of the three-hour period.

Discussion

All cases in this series were clinically shown to have the usual criteria of bacterial endocarditis: fever, heart lesion, and embolic phenomena in at least two different systems. In view of the fact that a transient bacteraemia can occur in patients with heart lesions who have no bacterial endocarditis, the above signs were demonstrated in addition to positive blood cultures (*Str. viridans*) before a case was treated. In spite of a severe and protracted debilitating illness coupled with the discomfort of up to a month's three-hourly intramuscular injections, all the patients remained extremely cheerful and of bright mentality: the "spes endocarditica" of Horder (1920).

The commonest superficial evidence of embolism was found in the form of splinter haemorrhages beneath the nails, occurring in 15 cases, in contrast to Osler's nodes, which were found in 9 patients. These embolic phenomena occurred most frequently in the first week of treatment, but also in several cases up to one month after treatment. In three cases lesions were noted in the palms of the hands; presumably embolic in nature, they presented suddenly as a tender raised nodule the size of a pea, and made all movements of the fingers painful. In two days the pain was less noticeable, but the fingers of

the affected hand showed some degree of flexion deformity, with complete inability to extend them actively. This was soon overcome with massage and passive movements, as probably due to involvement of palmar fascia.

Palpable splenic enlargement was present at some stage of the illness in 13 cases. In 7 patients the spleen rapidly diminished in size, not being palpable after 10 days' treatment. The degree of enlargement and the time it remained palpable were approximately proportional to the duration of the disease. Although 3 of our patients have shown transient visual disturbances such as blurring of vision, none have had white spots in the retina—so-called Roth spots. There was no optic neuritis or papilloedema. Clubbing of the fingers was present in 15 patients, in three of whom it appeared to be less marked after their discharge from hospital than on admission.

On admission all patients had an anaemia of microcytic hypochromic type which varied between 36% and 82% haemoglobin, mostly between 55% and 70%. In only 6 patients was the leucocyte count above 10,000 cells per c.mm., and one case showed the frequently described increase in large mononuclears, here 1,500 in a total white count of 8,800. An increase in the haemoglobin percentage occurred along with other signs of improvement—e.g., increase in weight, diminished evidence of embolism, fall in sedimentation rate. The B.S.R., estimated by Wintrobe's method corrected for packed-cell volume, was invariably raised at the outset, and showed a slow but steady fall, remaining abnormally high during the stay in hospital, and returning to within normal limits only some three months after treatment.

Microscopical haematuria was found in all cases, macroscopic in two, one of which showed clinical signs of a renal infarct of some magnitude. Ten patients continued to have a small number of red blood cells in the urine—one case five months after the end of treatment. This persistence of blood cells does not appear to be associated with any impairment of renal function at the present state of follow-up. In Bell's (1932) series over 50% of kidneys in endocarditis showed embolic focal nephritis; a smaller percentage had a diffuse acute or chronic glomerulonephritis. Since there may be a considerable time-lag between the onset of these lesions and the time when signs of renal impairment manifest themselves it is probable that, in the future, cases cured of endocarditis will show impairment of renal function.

A typical café-au-lait colour was noted in only 5 patients, probably because the majority started treatment within the first few months of onset. Three patients suffered cerebral damage from embolism—two of these within the first three days of treatment, one before treatment was started. It is worthy of note that the two relapses occurred early—i.e., within six weeks of terminating treatment.

Dental extraction can almost certainly be cited as the determining factor in initiating the infection in 3 patients who first noticed symptoms immediately after this procedure. A further 9 patients showed signs of dental infection. That oral sepsis may be a determining factor in initiating subacute bacterial endocarditis has been amply demonstrated by Okell and Elliott (1935), who found a transient bacteraemia after teeth extraction in 30 out of 40 cases with marked gum disease, and also obtained positive blood cultures in 12 of 100 cases of oral sepsis without the added trauma of extraction. There can therefore be no doubt that the most stringent oral hygiene is essential in persons with congenital or rheumatic heart affections. In our cases a rigorous search was made for septic foci, and these were eradicated in order to prevent reinfection.

In this series the disease has been completely arrested for periods of two to ten months, as judged by a gain in weight, normal temperature, disappearance of anaemia, absence of leucocytosis, diminution in the number of red cells in the urine, and fall in the sedimentation rate. Three of the four deaths resulted from causes not amenable to chemotherapy—i.e., ruptured aortic valve, cerebral embolism, and cirrhosis of liver.

Until penicillin was used in the treatment of subacute bacterial endocarditis this dread disease carried a mortality of close upon 100%. We now feel definitely more hopeful, or even confident that means of curing this condition are within measurable reach.

Summary

Eighteen cases of proved subacute bacterial endocarditis treated with penicillin are described. There is reasonable hope of permanent cure in 11 instances. There were four deaths, but only one can be called a failure to respond to penicillin. In three cases it is as yet too early to claim permanent recovery.

We should like to thank the Medical Research Council for providing penicillin for this investigation, and Mr. J. W. Schofield, the dental surgeon, for his advice and treatment of the teeth in the case mentioned above; also Prof. J. McIntosh for his help and advice.

SYMPATHECTOMY IN PERIPHERAL ARTERIOSCLEROSIS

BY

E. D. TELFORD, F.R.C.S.

Emeritus Professor of Surgery, University of Manchester

AND

H. T. SIMMONS, Ch.M., F.R.C.S.

Research Fellow, Manchester Royal Infirmary

(From the Neurovascular Clinic, Manchester Royal Infirmary)

The ischaemia to which the ill effects of arteriosclerosis are due is caused partly by the thickening and narrowing of the vessel and partly by thrombi deposited on the altered intima. The damage may be made worse, sometimes acutely so, by the impaction of emboli from above, and there is also evidence that spasm of the diseased vessels may play some part in aggravating the trouble.

If the mischief were evenly and progressively spread throughout the arterial tree the sequence of mishaps would be coldness, claudication, rubor, rest-pain, persistent deepening cyanosis, and eventually onychia, ulceration, or gangrene. Such a sequence is in fact, seen in a number of cases, but the complexity of branches, the proneness to disease of certain areas, and the wide differences in the ease with which collateral circulation can be established lead to much divergence in both the order and the severity of symptoms. For instance, an obstruction in the more proximal stretches of the supply may cause only a moderate claudication going on for years without further trouble, whereas an obstruction in the popliteal area not only may cause severe claudication but may gravely imperil the life of the leg. Again it is not uncommon to find severe digital thrombosis with palpable posterior tibial pulse and no claudication. These latter cases may be due to the silting up of the vessels by repeated minute emboli and are apt to go to the bad rapidly with few or no premonitory signs. Such wide variations not only make prognosis difficult but render it far from easy to estimate the value of any given line of treatment.

In view of the poor results of medical treatment, with its expectant attitude, we have attempted over a number of years and on many different types of cases to find out what results might be obtained by the practice of sympathectomy on these patients. Division of vasoconstrictor fibres might be expected to lead to an improved supply partly by dilatation of the vessels and partly by improving collateral channels, provided always that the vessels were not too far damaged to permit of a response. Further, if it be true that spasm is a factor, any spastic contribution would be lessened or entirely eliminated.

For the purpose of this paper the word "sympathectomy" means either a cord-ganglionectomy of the lumbar chain, one and a half to two inches (4-5 cm.) in length, centred opposite the third lumbar vertebra, or, for the upper limb, a section of the thoracic chain below the third rib with wide dislodgement of the cut ends.

Scope of the Inquiry

The period over which the work extends is 15 years and the number of patients operated upon is 98. There were only seven women in the series. The consequences of arteriosclerosis are no doubt much less common in women than in men, but the

proportion of 91 males to 7 females is due to the fact that the man more often seeks advice than does the woman because of the interference with wage-earning. The average age of the patients who came on account of intermittent claudication was 50 years, while of those suffering from gangrene the average was 56. The complications of arteriosclerosis are to be found at ages much younger than is generally supposed. Our youngest patient was a man aged 32 who came to amputation owing to gangrene of the foot due to thrombosis of an ulcerated, calcified popliteal artery. The immediate post-operative mortality was small in view of the bad surgical risks of this type of patient. There were four deaths—one from alcoholic delirium, one from a profuse haematemesis due to a duodenal ulcer, and two from pulmonary embolism.

The follow-up has been very thorough; only three of the cases are untraced. Twelve of the patients are known to have died and, as might be expected, the cause of death in ten of these has been certified as either "angina" or "coronary thrombosis." No case of diabetes is included in the list.

Of the 91 cases left for analysis, 88 were in the lower extremity and 3 in the arm. The sympathectomy was bilateral in 46 cases and unilateral in 45, thus providing for review the not inconsiderable number of 137 limbs. The 88 cases in the lower limbs may be further subdivided into 47 in which the operation was done for intermittent claudication and 41 in which the reason for operation was incipient or frank gangrene.

Results in Intermittent Claudication

The post-operative history of these 47 cases is on the whole disappointing. They were all severe examples with claudication of the order of 25 to 50 yards (23–46 m.), and although not one has failed to show some improvement the majority have gained no more than 50 to 100 yards (45–90 m.). Nearly all say that the period of rest before they can go on again has been shortened and that the pain is not quite so acute. While this kind of result would hardly justify a major operation, it is gratifying to find that not one of these patients who have been followed for from 5 to 15 years has developed rest-pain or gangrene.

Though the average result has not been encouraging we find that six of these 47 cases were so far relieved as to become almost normal. One man returned to a heavy insurance round and walked many miles each day until he died suddenly from a coronary thrombosis. Another returned to his work and could walk any reasonable distance, but not uphill. This man was found at operation to have a complete obstruction of the aortic bifurcation. In the other successful cases the thrombosis was highly placed. These results are in agreement with an old observation that sympathectomy has given its best results in high obstructions. It may be possible by further study and experience to select with greater certainty the type of case that is likely to do well after operation.

Should operation be decided upon it should in all cases be bilateral, although complaint is usually made of one leg only; this is because the worse leg pulls the patient up before claudication can develop in its fellow. If these patients are tested by a claudicometer the second leg will usually be found to be little better than the one of which complaint is made.

Results in Cases with Gangrene

Since in arteriosclerosis there can be no question of a cure, the results in this group have been classified as "good" and "failed." By good is meant the abolition of rest-pain, the change from chronic invalidism to a life of reasonable activity, and the separation and healing of minor gangrenes. Judged on these lines the results in 21 cases were good, while in the remaining 20 the operation did not succeed and some form of amputation had to be done. We would point out, however, that in a sympathectomized limb it is often possible to perform a much less radical amputation than the customary one through the lower third of the thigh. A more detailed examination brings out the fact that without exception all the cases which gave good results were the earlier ones with rest-pain, persistent cyanosis, onychia, or minor gangrene of one or two toes.

A successful result depends upon the patency of a sufficient number of digital vessels. If the extent and degree of digital thrombosis are severe a good result is unlikely, and in doubtful

cases preliminary spinal analgesia or a paravertebral sympathetic chain block should be done to estimate how far the circulation can be restored. The cutting out of the constant wearing rest-pain after operation is often dramatic, but is seen only in those cases in which the operation has caused a definite improvement in the circulation. All the 20 cases which failed to show any improvement were instances of frank gangrene of two or more toes, or of the heel or dorsum of the foot.

It seems clear from these results that there is one stage in the downward progress of these patients at which sympathectomy may be usefully done. The time for it is the stage of rest-pain with deep rubor blanching rapidly on elevation or with persistent cyanosis. No more than trivial and superficial black patches should be present, but onychia can usually be got to heal.

If gangrene is more than trivial in extent, and especially if it be complicated by infection, the operation should not be done. In fact, two of the patients in our series showed a distinct and disquieting extension of the trouble after sympathectomy.

The Upper Extremity

The patients treated by sympathectomy for the complications of arteriosclerosis in the upper limb are too few to warrant any conclusions. They were, one case of thrombosis of the brachial artery and two cases of severe and crippling Raynaud's syndrome such as is sometimes seen in the hands of older and, more often, women patients. All three gave very good results. This is what one would expect from the better blood supply and more free anastomosis of the upper limb; it has no area comparable to the popliteal for danger.

Summary and Conclusions

Sympathectomy is not likely to lead to any worth-while improvement in the majority of patients suffering from intermittent claudication. There are, however, occasional excellent results. These appear to be found in patients with more proximal thrombosis, and it may be that further observation and experience will make for greater confidence in the selection of cases for operation.

Sympathectomy has no place in the treatment of extensive gangrene, but has been found to be of much value in the earlier pre-gangrenous states—e.g. rest-pain, persistent cyanosis, and small local lesions.

PRIMARY LUNG CANCER IN CHILDHOOD

REPORT OF AN UNUSUAL CASE

BY

ARCHIBALD DICK, M.D., B.Sc.

Assistant Pathologist

AND

HUGH MILLER, F.R.C.S.Ed.

Honorary Surgeon

Royal Northern Infirmary, Inverness

The trend of opinion is that primary malignant disease of the lung is increasing; whether the increase is apparent or real is a question on which there has been no little controversy. The great majority of patients suffering from this disease are between the ages of 40 and 60. Thus Davidson (1930) recorded 107 cases of primary lung cancer with only two patients under 21 years, while Duguid (1927) described 173 cases with five under 21 years. Fried (1931) described 47 cases with only one patient between 20 and 29 years. References to primary lung cancer in childhood are still rare, and they are often unsatisfactory in that the origin of the primary growth is not always established. The diagnosis in childhood is often difficult; the following recorded cases each present some interesting but unusual feature. Wasch *et al.* (1940) described a case of bronchogenic carcinoma of seven years' duration in a boy aged 11. Sommer (1934) suggested the possibility of carcinomatous degeneration in a congenital cyst in a child 7 years old. Jones *et al.* (1943) described asthma as a presenting symptom in a boy of 10 years having a papillary growth extending into the lumen of the right main bronchus. Beardsley (1933) described an adenocarcinoma in a child of 23 months in whom secondary deposits had been evident 13 months previously. Hauser (1942)

recorded the case of a child of 17 months who had been ill for five months before the exact nature of the condition was realized.

The case to be described, in which the primary growth was not evident until eight months after a secondary deposit had become manifest, illustrates clearly the difficulties in the diagnosis of primary lung cancer in childhood, and would appear to be worth recording.

Case Record

The patient, a girl aged 9, was first seen at the out-patient department on March 9, 1944, complaining of pain in her left thigh of two weeks' duration, worse when walking and varying in amount each day. There had been no systemic upset or other sign of infection, but her doctor suggested the diagnosis of osteomyelitis and had started treatment with sulphadiazine. On examination there was tenderness over the upper end of the left femur, but no swelling of the thigh and no limitation of movement at the hip or knee-joint. X-ray examination showed no lesion of either femur; the leucocyte count was 10,650. There did not seem to be enough evidence to support the diagnosis of osteomyelitis, and she was allowed home, to be under observation.

On April 11 she was admitted to the Infirmary for further investigation; the pain in her left leg persisted, and was even troublesome when she lay in bed. Her general condition was satisfactory and she was afebrile; the leucocyte count was 8,250. A skiagram of the left leg now revealed a circumscribed area of atrophy just below the epiphysal line of the greater trochanter; nine days later this atrophy was more pronounced, but at the end of two weeks no further change had occurred. The condition was regarded as an inflammatory process affecting the upper end of the femur, and the possibility of a tuberculous focus was kept in view. No member of the family had suffered from tuberculosis. Her symptoms improved somewhat, and she was allowed home on May 16, with the instruction to rest in bed.

The patient was readmitted six weeks later (June 26) complaining of fairly severe and continued pain in the left leg. Her general condition had deteriorated somewhat and locally there was swelling of the left thigh. X-ray examination revealed further destruction of the upper end of the femur extending towards the shaft; there was no periosteal reaction and the cortex of the bone remained unchanged. The radiological appearances suggested an acute medullary infection, yet this was not consistent with the relatively slight clinical upset. Haematological and biochemical investigations on June 30 showed: Hb, 80%; R.B.C., 4.34 millions; C.I., 0.92; W.B.C., 5,510 (neutrophils 57%, eosinophils 5.5%, lymphocytes 30.5%, monocytes 7%). Further differential counts on July 14 and 19 revealed an almost identical distribution of the blood cells. The urine contained no Bence-Jones protein. Serum: albumin 5.8 g. %, globulin 2.2 g. %, and calcium 10 mg. per 100 ml.

A reasonable diagnosis appeared to be that of subacute osteomyelitis of the femur, and operation was considered advisable. At operation on July 5 several drill-holes were made into the bone and necrotic material was removed. Histological examination of this material revealed the presence of spicules and trabeculae of bony tissue separated by loose vascular connective tissue with masses of very cellular necrotic tissue, the cells of which could not be identified with certainty, but the lesion appeared to be neoplastic. There was no evidence of myeloma; and Ewing's tumour, another possibility, did not seem likely owing to the situation away from the mid-shaft and the absence of the typical radiological appearances of this tumour. A skiagram of the chest at this time (July 12) showed: "Enlarged partially calcified hilar and peribronchial glands, with peribronchial thickening in upper lung fields."

From July 14 to Aug. 25 the patient received deep x-ray therapy to the left femur; kilovoltage, 200; dose in r units, 2,000. By July 27 the disease process seemed arrested and showed commencing sclerosis with a periosteal reaction on x-ray examination. By Sept. 19 the process appeared to have "healed" and there was much sclerosis in the affected area; there was also slight atrophy of the head of the femur and a tendency to coxa vara. The child had no pain and was able to walk freely. We felt gratified at the response to x-ray therapy and the patient was dismissed on Sept. 23; the diagnosis was still uncertain and the prognosis doubtful.

On Nov. 10, eight months after she was first seen, the patient was readmitted complaining of cough, headache, and vomiting. She was emaciated and very breathless; there was found to be marked dullness of the right side of the chest, the clinical findings suggesting a right-sided pleural effusion. Aspiration of the chest revealed only a small quantity of blood-stained fluid which contained a few lymphocytes and some endothelial cells; there was no evidence of neoplastic cells. Further aspiration was attempted, but very little fluid was obtained, and the appearances were those of a needle entering solid lung or tumour tissue. The diagnosis was that of a malignant condition of the right lung, probably secondary to the obscure condition of the femur. X-ray therapy to the chest was

carried out from Dec. 12 to 22, by which time the general condition did not permit of further treatment. The patient died on Jan. 4, 1945.

Necropsy Findings.—The body was that of a very thin emaciated girl. The mediastinum was enlarged and was displaced to the left. The right lung was almost entirely replaced by a large mass of necrotic malignant tissue arising from the upper main bronchus. The tumour had invaded the chest wall and the mediastinum. The left lung and the heart, apart from displacement, presented a fairly normal appearance. The abdominal viscera were all free from the neoplastic process. The upper end of the left femur was replaced by yellowish necrotic tissue, which on the lateral surface extended to the periosteum, and the cortex of this part of the bone was considerably thinned. Histological examination of the lung revealed the presence of a primary bronchial carcinoma of the anaplastic type which had involved the whole of the right lung. The lesion in the femur was of similar histological structure.

Discussion

This case of primary lung cancer in childhood, in which the correct diagnosis was not established until necropsy, presents several interesting features. Histological examination of the necrotic material from the bone first suggested the possibility of a neoplastic process; the local response to x-ray therapy was satisfactory, and substantiated this diagnosis. When the patient returned to hospital presenting pulmonary symptoms the first impression was that she had secondary deposits in her right lung causing a massive effusion. (It should be noted that a skiagram of the chest four months previously had revealed no evidence of a bronchial neoplasm.) The radiological appearances of the chest were now consistent with those of a massive pleural effusion, and it was not until a second aspiration was attempted that the nature of the lesion was recognized. Hauser (1942) had previously observed that a sufficiently large tumour causing displacement of the mediastinum may resemble an effusion. Having established the presence of a large lung tumour, it still seemed likely that the pulmonary lesion was secondary to that in the bone. As was stated by Florman (1943) metastatic tumours in the lung in childhood are less rare than primary tumours, since many neoplasms occurring in early life invade the blood stream and become seeded in the lungs. The primary lesion, which had remained unrecognized for eight months, was, however, found to be a bronchial carcinoma, and the lesion of the right femur was secondary. Allen and Smith (1932) have pointed out that metastatic tumours may give rise to symptoms before the original site is suspected of disease, but it is most unusual to find a primary bronchial carcinoma giving rise to a single secondary deposit in bone. We doubt if the correct diagnosis could have been established at an earlier stage there was nothing to suggest a pulmonary lesion until one month before death. This case therefore stresses the likelihood of early metastases, but unfortunately offers no clue to the cause of the growth.

Summary

A case of primary lung cancer in a girl aged 9 is described. A single metastasis in the left femur caused symptoms eight months before the pulmonary lesion was recognized. The difficulties in the clinical and radiological diagnosis of the condition are discussed.

We wish to thank Dr. Gollied of the radiological department for his help with this case.

Reviews of current literature bearing on various aspects of child welfare, by specialists in their own subjects, are a feature of the March issue of *The World's Children* (20, Gordon Square, London, W.C.; 6d.). Dr. H. Mannheim, of the London School of Economics, writes on juvenile delinquency and the law; Mr. F. Le Gros Clark on science and nutrition; and Dr. R. G. Gordon on problems of adolescence. Mr. John Morgan considers the National Insurance Bill from the point of view of its relation to children and family welfare; Dr. Harold A. Moody discusses the problem of illegitimate children of English mothers and American negro troops; and Dr. R. P. Stewart, writing from Greece, deals with the question of nutrition in that country.

SURVIVAL OF CORTICAL BONE AFTER BONE-GRAFTING

BY

DAVID BROWN, M.Ch.Orth., F.R.C.S.Ed.

*Orthopaedic Surgeon, the Royal Infirmary and Children's Hospital
Sunderland*

Since the earliest days of bone-grafting there has been doubt whether any of the cells of the graft survive. Until recently this subject was thought to be largely of academic interest because cortical bone had been used as a graft almost exclusively, and it had often been noted that a cortical graft was just as successful in promoting union whether it was transplanted alive or had first been killed and sterilized by boiling.

A change has recently taken place in surgical opinion on this subject, notably as a result of the work of Mowlem (1941), who was able to secure histological specimens of iliac-bone grafts four or five months after their insertion for repair of the bridge of the nose. These sections seemed to show that transplanted cancellous bone transformed itself into cortical bone within the short space of four months after operation, and that the cells in this bone remained alive; while transplanted cortical bone remained cortical in structure, its lacunar cells appeared dead, and it had not yet been replaced by living bone five months after the operation.

It was concluded from these interesting observations that cortical bone was too dense to allow the passage of sufficient tissue fluid to nourish the lacunar cells. A tibial cortical graft might therefore be expected to die and be gradually replaced by creeping substitution from the adjacent bone, while its function in a bone-grafting operation was simply to act as a splint and as a source of readily available calcium. Cancellous bone, on the other hand, was regarded as of so spongy a structure that it could be permeated by tissue fluids and so survive after transplantation.

The truth of these observations has since been abundantly tested, and Higgs (1945) was able to quote comparative figures for bone grafts which indicated that osteogenesis was more rapid in those cases where a graft of cortical bone was combined with the use of cancellous chips than where cortical bone was used alone.

It seems of interest in this connexion to quote three cases of bone tumours which have been excised extraperiosteally and replaced by a tibial cortical bone graft. In each case the graft has apparently survived without showing any evidence of being

replaced by creeping substitution, while in one case a fracture of the graft with subsequent union took place

Illustrative Cases

Case 1.—Female aged 18: a case of rapidly growing enchondroma of the proximal phalanx of the right thumb which had recurred following incision and curettage. Operation (Feb. 1, 1940) consisted of extraperiosteal excision of the whole proximal phalanx of the thumb and replacement by a tibial cortical graft sharpened at each end and inserted between the raw base of the distal phalanx and the head of the metacarpal bone of the thumb. Union of the graft had taken place at both ends by June 26, but a month later the union at the distal end broke down and a false interphalangeal joint began to form. When last seen on Dec. 8, 1943, the graft, which remained strongly united at its proximal end, was composed of strong bone throughout, and the false interphalangeal joint had acquired 30° of active flexion and extension. At present, nearly six years after the operation, the patient reports that her thumb remains as good as when she was last seen in 1943.

Case 2.—Female aged 24: a case of osteoclastoma of the lower end of the left radius which recurred after curettage. Symptoms were first noticed when the patient suffered a fracture through the tumour during an epileptic fit. Operation (Oct. 31, 1941) comprised incision over the postero-lateral surface of the hand and lower end of the forearm; separation of tendons and nerves from the front and back of the wrist-joint; division of the wrist-joint capsule so as to allow the hands to be capsized ulnarwards, hinging on the ulnar collateral ligament; extraperiosteal removal of the whole lower end of the radius with the pronator quadratus muscle; and replacement by a large tibial cortical bone graft inserted into the split lower end of the radius and the denuded proximal surface of the carpus. During the operation the tendon of the extensor pollicis longus was ruptured; this was made good by transplanting the extensor carpi radialis longior into the distal end of the thumb extensor.

On April 23, 1942, the graft was regarded as united strongly enough to allow removal of the plaster, but, in view of the patient's epilepsy, she retained an aluminium splint on the arm for several months longer. On Dec. 28, 1942, she complained of pain in the wrist, and a skiagram showed a crack in the lower end of the graft. It was assumed that she had refractured the graft during a fit. The wrist was immobilized again in plaster. Union of the fracture subsequently took place, though the graft shortened during the process of the union and allowed radial deviation of the hand. At present, four years after the operation, the graft remains united at both ends, and at the site of the fracture.

Case 3.—Female aged 36: a case of osteoclastoma of the lower end of the right radius. The operation (March 20, 1944) was essentially the same as in Case 2, except that the tendons of the extensor pollicis longus and abductor pollicis longus were deliberately divided and later resutured. Uneventful union of the graft took place by October, 1944. At present, 19 months after the operation, the skiagram shows sound union at both ends of the graft with good-quality bone intervening

FIG. 1.—Case 1. A, Enchondroma of proximal phalanx of thumb. B, Five months after extraperiosteal excision and replacement by bone graft: union both ends of graft. C, Fifteen months after operation: false joint forming at distal end of graft. D, Three years and ten months after operation: actively movable false joint at distal end of graft.

FIG. 2.—Case 2 A, Osteoclastoma of lower end of radius. B, Six months after extraperiosteal excision and replacement by bone graft. C, Fourteen months after operation: fracture of graft. D, Four years after operation: fracture remains united.

FIG. 3—Case 3 A, Osteoclastoma of lower end of radius. B, Four months after extraperiosteal excision and replacement by bone graft. C, Seven months after operation. D, Nineteen months after operation.

Comment

These grafts have evidently not received any assistance from the periosteum in their survival, since in each the periosteum of the recipient bone was completely removed with the tumour and the bone graft was inserted without any periosteum attached to it. Neither can it be said that these grafts have been replaced by creeping substitution from the bones with which they were in contact. If this had been the case one would have expected radiological evidence in the form of a decalcified line of demarcation gradually spreading from the ends towards the centre of the graft.

It might, however, be argued that these grafts died and were replaced by an invasion of cells from the organizing haematoma which surrounded them, such cells subsequently becoming differentiated into bone elements. This suggestion

it is impossible to refute, and it is in line with the teaching of Leriche and Policard that bone may form wherever there is a mass of primitive mesenchyma and an adequate supply of blood and calcium. But why postulate a difficult theory in these cases when it can be more simply assumed that at least a proportion of the bone cells of the original graft survived and proliferated?

Certain radiological appearances were common to each of these grafts. First, the coarse trabeculation of the original tibial graft became gradually transformed into bone of a denser and more finely trabeculated structure. Secondly, each case shows evidence of the development of a surface layer of homogeneous bone, as if the graft was attempting to differentiate itself into cortical and medullary structure. These radiological appearances seem to indicate that there was at least partial survival of cells throughout the whole substance of the graft.

The most important common factor in these cases, however, appears to be that each graft was transplanted into an area richly supplied with blood and devoid of any scar tissue. It would seem that when transplanted into such ideal surroundings even a cortical bone graft will survive and will rapidly become incorporated in the circulation of the host. These cases appear to emphasize once again that one of the chief functions of a bone-grafting operation must be the removal of scar tissue and the opening up of the whole vascular area for the promotion of osteogenesis at the site of fracture.

ARGENTAFFIN (CARCINOID) TUMOURS OF THE SMALL INTESTINE

BY

A. ANDERSON BONAR, M.B., F.R.C.S.E.

Surgeon, Ashington Hospital

Argentaffin tumours are most commonly met with in the appendix, but it is now well recognized that they may occur in any part of the gastro-intestinal tract. According to McLeod (1944) about 283 cases of carcinoid tumours of the small intestine had been reported in the literature up to May, 1944. There is general agreement that, after the appendix, the most common site is the terminal ileum.

Carcinoid tumours of the appendix are generally stated to be innocent, but in the ileum the behaviour is quite different. Humphreys (1939), reviewing 152 cases, found that 37 (24.4%) had metastases. Dangremond (1942) in a study of 46 cases found that 24 (52%) had metastases. Ariel (1939) tabulated 111 cases of carcinoids reported in the literature since 1930. In this series metastases were reported in 33 cases (29.7%). Obviously, therefore, the tumour as found in the small intestine may behave as a metastasizing malignant growth, calling for radical surgical treatment.

Case Report

Mrs. P., aged 52, was admitted to hospital on April 24, 1943. The provisional diagnosis was chronic appendicitis. The history was that in the last two years she had had intermittent attacks of abdominal pain—five in all. The last attack occurred 14 days before admission. Each attack started with pain, at first felt in the right iliac fossa, but gradually spreading over the abdomen. When asked about the radiation of the pain, she stated that it tended to travel in a direction roughly following the course of the colon. The pain was of a colicky type. During each attack the bowel was constipated. The pain was severe enough to make her go to bed. On only one occasion did she vomit, though she often felt nauseated. Each attack lasted about four days. An interesting statement was that after the attack she invariably had diarrhoea. She was not certain as to the presence of distension during an attack. Examination was largely negative. She appeared to be a healthy woman, perhaps rather stout. The skin was clear, and there was no jaundice. The mucous membranes were well coloured and the tongue was clean. No abnormality was detected on examination of the chest and cardiovascular system. The urine was normal. The abdominal wall was rather stout and the muscles were flabby. No masses were palpable. Slight tenderness was noted in the right iliac fossa, and there was unusual gurgling. P.V. and P.R. examinations were negative.

In view of the history of ? obstructive attacks a barium enema x-ray examination was advised. This was carried out by Dr. D. Ramage, who reported as follows: "Apparently a developmental anomaly of the colon. The right flank is empty of colon; the caecum and ascending colon are near the midline. There is no evidence of filling defect." This unexpected report raised the question of recurring volvulus as an explanation of the symptoms, and operation was accordingly advised.

Operation was carried out on May 10. The abdomen was opened by an oblique muscle-cutting incision in the right iliac fossa. The caecum and ascending colon were found to have well-developed mesenteries. There was no distension of the caecum. The appendix was healthy. On further investigation a lesion of the ileum was found. The last few inches of the ileum were distorted by adhesion, and on palpation a hard mass was felt in the centre of the adherent bowel. The bowel proximal to the tumour was not distended. A presumptive diagnosis of scirrhus carcinoma was made. The mesenteric lymph nodes were not enlarged, and no secondary deposits were found in liver or peritoneum. In view of the proximity

of the growth to the caecum, a radical ileocelectomy was performed, and the ileum anastomosed to the transverse colon by the side-to-end method. No difficulty was encountered, as the colon was extremely mobile. The wound was closed, with drainage. The patient made an excellent recovery, despite some wound sepsis. She was discharged home on June 5, and has remained in excellent health since.

The specimen, unopened, was sent to Prof. A. Bernard Shaw for opinion, and he reported as follows:

"The specimen consists of the lower end of the ileum, 16 cm. long, the caecum and ascending colon, and the appendix. The attached mesenteries are loaded with fat, and the site of extensive operative haemorrhage. At 4 cm. from the ileo-caecal junction there is a transverse constriction on the outer aspect of the ileum. Embedded in the constriction is a hard mass 2 by 5 cm., which projects into the lumen of the ileum. The opaque bright-yellow material constituting this involves the submucosa and subserosa, while the muscular coat passes through it. The appendix shows no gross change. Microscopically, this is an argentaffinoma of the ileum which has infiltrated the muscular and subserous coats. The neoplastic cells give a positive reaction to Masson's silver stain, thus establishing the identity of the tumour."

Discussion

It is not proposed to discuss the pathological histology of these tumours. Masson's theory (1928, 1930) that these tumours arise from the Kultschitzky cells of the crypts of Lieberkühn, appears to be generally accepted. The cells contain granules which acquire a dark-brown stain when treated with Masson's silver stain—hence the name "argentaffinoma." The most striking feature of these tumours is the bright yellow colour on section. Usually the growth projects into the lumen of the bowel as a smooth polypoidal mass, and obviously this may lead to attacks of intussusception. Occasionally the tumour takes an annular form, giving rise to a typical ring constriction of the affected bowel.

It is obvious from personal experience that these tumours are rare. Raiford (1933) recorded 29 carcinoid tumours—9 of the ileum—as occurring in 62,000 necropsy and surgical specimens examined at the Johns Hopkins Hospital. Ariel (1939) examined 47,045 specimens at the Mount Sinai Hospital, and found 31 carcinoids.

The appendix and the terminal ileum are the two most frequently affected sites in the gastro-intestinal tract, but, as mentioned above, there is a striking difference in the malignancy of the two types. All commentators are agreed that carcinoids of the appendix are innocent. But in the ileum there is no doubt that the tumour is almost as malignant as an adenocarcinoma. Quarry Wood (1936), quoting Humphreys, points out that the incidence of metastases in carcinoids of the ileum is 24.4%, whereas the frequency of metastases in adenocarcinoma is given as 38% by Schlepps. In Quarry Wood's case a lymph node 2.5 cm. from the growth was the seat of a metastasis. McLeod cites one case in which the wall of the caecum was invaded, and a second case in which a mass of tumour cells was found in a large blood vessel of the mesentery. In the case under discussion the tumour cells had infiltrated the muscular and subserous layers. Ariel sums up the question of metastases thus:

"Metastases usually occur in the regional lymph nodes, the mesenteric fat, and, to a lesser degree, the liver. . . . Metastases have been recorded as follows: 29 in regional lymph nodes, 10 in the liver, 9 in the mesentery, 2 in the peritoneum, 1 in the inguinal lymph nodes, 1 in the peripancreatic and retroperitoneal lymph nodes, 1 in the testis, and 1 in the dura mater with compression of the spinal cord."

From the clinical viewpoint, the most common picture is one of recurring attacks of intestinal obstruction. The diagnosis arrived at on clinical grounds is most likely to be carcinoma of the colon, but the barium enema x-ray will negative this. It may be possible on x-ray examination to diagnose an obstruction of the terminal ileum, as in Quarry Wood's case, but many of the cases in the literature were not accurately diagnosed before laparotomy. In the case under review the presence of a gross congenital abnormality of the colon added to the difficulties, and, as mentioned, volvulus of the caecum was considered as a possible explanation of the symptoms.

In view of the evidence as to the malignancy of the tumour treatment must be radical, and as many of the growths are very close to the caecum an extensive resection of gut is necessary. The prognosis depends on the presence or otherwise of irremovable metastases. In the literature, only one reference to

the effect of x-ray therapy on these tumours was found, and unfortunately there was no final proof as to the nature of the tumour. The case is reported by Ariel (1939). A patient had had a resection of gut performed for a tumour of the terminal ileum, and section proved the growth to be a carcinoid. There were no metastases in the liver. Two months later a mass was found in the right iliac fossa, and a diagnosis of local recurrence was made. Deep x-ray therapy was given, and the mass disappeared. Ariel was of the opinion that the mass was a definite recurrence, and no doubt there were good reasons for coming to such a conclusion, but one cannot dogmatize, from this suggestive case, as to the value or otherwise of x-ray therapy in these growths.

Summary

A case of argentaffinoma (carcinoid tumour) of the ileum is reported.

These tumours are found most frequently in the appendix and the ileum. In the appendix they do not metastasize, but in the ileum secondary deposits are met with in 25% of cases.

The clinical picture is one of repeated attacks of intestinal obstruction.

The pre-operative diagnosis is difficult, and if an obstructive lesion of the terminal ileum is found it is most probable that it will be labelled carcinoma.

The appropriate treatment is radical removal.

Medical Memoranda

Spontaneous Rupture of the Heart associated with a Road Accident

Two men were brought in dead to an East African military hospital with a history of having been knocked down by a lorry. Necropsies were performed within three hours of death, revealing in one of them extensive multiple fractures of the skull with severe laceration of the brain. The post-mortem findings in the other are described below.

FINDINGS AT NECROPSY

The body was that of a European male aged 40, about 5 ft. 7 in. (1.7 m.) tall, weighing between 12 and 13 st. (75–80 kg.). The chest, abdomen, and back were well covered with fat, which had a depth of 1½ in. (3.8 cm.) over parts of the abdominal wall. There were several superficial skin lacerations on all four limbs, particularly on the right arm and leg; the face was scratched and bruised.

Examination of the skull revealed a subperiosteal haematoma over the vertex about 1½ in. in diameter overlying a fracture about 1 in. (2.5 cm.) long, depressed at the anterior end. The brain and meninges were intact, and, except for some bilateral pinpoint petechial haemorrhages on the cerebral surface and in the white matter, no abnormality was found. The pituitary fossa and gland appeared normal. No other bone injury was seen, and no evidence of disease or injury was present in the tongue, pharynx, salivary glands, larynx, trachea, or thyroid gland. The thoracic wall was intact, and the lungs, pleurae, and bronchi showed no abnormality. The heart and pericardium are described below.

On opening the abdomen the striking feature was the gross amount of fat in the greater omentum; this was much in excess of what is normally found. The spleen, pancreas, gall-bladder, stomach, and small and large intestines appeared normal. The liver was enlarged one fingerbreadth below the costal margin, firm in consistency, and with a firm lower edge. The cut section was pale and greasy, revealing a fatty liver. Both kidneys were embedded in deep pads of fat, and the retroperitoneal fat was definitely excessive; the kidneys, suprarenals, ureters, and bladder seemed normal.

Heart and Pericardium.—The pericardial sac was globular, and was distended with about 1¼ pint (140 ml.) of blood. The heart was contracted and almost empty. Both auricles appeared normal. The fat of the ventricular epicardium was increased both in thickness and in extent. This was particularly evident on the anterior wall of the right ventricle, which was thin, being reduced to one-eighth of an inch (0.3 cm.) or less in parts. In many places the muscle bundles were separated by small areas of adipose tissue, which here and there almost formed the entire thickness of the ventricular wall. Streaky yellow patches of adipose tissue running along the lines of the columnae carneae were evident beneath the endocardium of the right ventricle, the cavity of which was dilated in spite of the general

contraction of the heart. Two linear ruptures were found in the anterior wall of the right ventricle communicating with the ventricular cavity, both about 1 in. long. The edges of the tears were uneven and irregular, but there was no evidence of recent bleeding or torn vessels along the edges, such as might be expected from a sudden rupture. One tear was situated about 1½ in. (1.25 cm.) from the anterior interventricular branch of the left coronary artery (to which both were roughly parallel), about 1½ in. (3.75 cm.) to the right of this artery, and 1 in. (2.5 cm.) above the inferior heart border. The ventricular wall was thinnest in the region of these ruptures, and consisted as much of fat as of muscle. There were no signs of disease in the valves, coronary arteries, or aorta.

Death was attributed to haemopericardium due to spontaneous rupture of the heart, with fatty infiltration of the myocardium, part of a general obesity, as the predisposing cause.

COMMENT

The relation of this unusual death to the road accident arose. Whether the head injury itself could have caused death was difficult to answer, but it seemed unlikely; yet just as difficult was the poser: Which came first—rupture or accident? The lack of recent bleeding along the edges of the rupture indicates that they had gradually formed and slowly progressed until they were well established on the day of the accident, but of course actual ventricular-pericardial communication had not occurred. It seems likely that completion of the rents was imminent at the time of the accident, and death was inevitable within, say, a few weeks. Completion of the ruptures may have occurred just before the accident by a sudden rise of inter-ventricular pressure due to fear or excitement. Alternatively, the accident occurred first, and the tears were completed, possibly, by the sudden contact of the chest wall with the ground.

Herpes Zoster in an Isolated Community

The question of the relationship between the viruses responsible for herpes zoster and varicella has recently been discussed in these columns by Dr. James Taylor (*B.M.J.*, 1945, 2, 385). That such a relationship exists is beyond dispute; there can be few general practitioners who have not observed an outbreak of chicken-pox following a case of herpes zoster, or the appearance of zoster in a household afflicted by chicken-pox. The implication that herpes zoster is always caused by the virus of chicken-pox cannot, however, be accepted.

CASE HISTORIES

On the island of Tristan da Cunha, in the South Atlantic, there live some 220 persons, none of whom have ever suffered from varicella or any of the other exanthemata or infectious fevers. In 1942 their isolation was disturbed by the arrival of a party of Naval and South African personnel and the establishment of a station on their island. In May, 1943, I saw there a case of herpes zoster in a woman aged 70; the eruption was typical, and occurred over the outer side of the upper third of the right thigh. Such a condition had not been seen before by the islanders. There was no doubt as to the diagnosis.

The anticipated sequel—an epidemic of varicella—did not occur. No further cases of herpes were seen until December, 1943, when a man aged 79 developed typical lesions of intercostal distribution. Again no chicken-pox followed; but 3½ months later—in March, 1944—a third case occurred. The patient was a man aged 33, and the distribution was again intercostal. There had been no further cases when I left the island in July, 1944, nor had there been any case of chicken-pox.

All three patients made an uneventful recovery and the constitutional disturbance was not severe. Post-herpetic neuralgic pain occurred in one case; it was not severe, and lasted for some two months only.

COMMENT

If ever there were conditions in which an epidemic of chicken-pox might be expected to follow herpes zoster, they were present at Tristan da Cunha. Neither man, woman, nor child had any acquired immunity to the virus, and the people were living crowded in ill-ventilated, often dirty, two- and three-roomed cottages, yet no varicella occurred.

My interpretation of the above events is that herpes zoster can be caused by neurotropic viruses other than the virus of varicella. The interval which elapsed between the cases is grossly in excess of the alleged normal incubation period. It would appear, therefore, that there was present on the island, presumably among the Service personnel, a carrier of low-grade neurotropic virus, the virulence of which was not sufficient to cause any morbid condition among the naturally immune new-comers, but sufficient to produce typical herpes zoster among the non-immune islanders.

 Surg. Lieut.-Cmdr., R.N.V.R.

Reviews

ON GROWTH AND FORM

Essays on Growth and Form presented to D. Arcy Wentworth Thompson
Edited by W. E. Le Gros Clark and P. B. Medawar (Pp 403, illustrated
21s.) Oxford: The Clarendon Press 1945

D. Arcy Wentworth Thompson was appointed professor of biology at Dundee in 1884, and has held a chair at St. Andrews since 1897. Any critic who might complain 'Sedet, aeter numque sedebit' is conclusively answered by the new edition of *On Growth and Form* published in 1942, and running to 1124 pages. This book reminds me of Greek geometry. I admire its elegance and ingenuity, but it is not always obvious what to do next. So often the author seems to have said the last word.

But the first edition, published in 1917, is at last beginning to bear intellectual fruit and the volume before us is part of its harvest. The longest article, and that which will probably be of the greatest interest to medical readers, is that on nerve fibres, by J. Z. Young. This summarizes his own work and that of his colleagues during the war, which has already had some influence on surgery. He makes out a strong case for the view that a nerve fibre is a hollow tube containing fluid under pressure, due to the fact that the nerve cell is continually forcing more fluid along it. If the internal pressure falls off the whole system breaks down, and the details of the breakdown are physically intelligible. Regeneration occurs at a roughly constant rate of about 4 mm a day, and is due to a steady outflow of material from the body of the nerve cell. So far everything is mechanistic. But fibres which make connexion with end organs hypertrophy, and those which do not do so disappear. So the author concludes on a decidedly unmechanistic note.

Prof. Le Gros Clark gives a similar mechanical analysis of the pattern of the folds in the cerebral cortex, and Dr. Danielli gives some very interesting facts regarding the surface forces in single cells. Dr. Astbury's article on molecular structures is an invaluable summary of the work which he and his colleagues have done on proteins, nucleic acid, polysaccharides, and other cell constituents. This work has only started, but the results are sufficiently striking. The fibrous proteins fall into two groups with different structures: an elastic group generally found inside cells, and including myosin, keratin and fibrinogen, and an inelastic collagen group always found outside cells, including the proteins of tendon, cartilage, and fish scales. Many of the non-fibrous proteins—for example, egg albumin and casein—can be drawn out into fibres of the intracellular type, but lose their specific properties in the process. When we know as much about their structure in the globular form as we know about it in the fibrous form we shall probably understand how they manage to be specific as enzymes or antigens.

Dr. Woodger's paper is an attempt to give a logical basis to the notion of homology. I can best explain why I distrust it by quoting one sentence: "Consider any such time-slice of a zygote and the set of all time-slices which are exactly like it." I may be wrong, but I start out from the assumption that no two animals are exactly alike. If I am right, Dr. Woodger's logic will not solve the problem. If a physician has ever had two patients who were exactly alike he will agree with Dr. Woodger, if not, not.

Reeve and Huxley, Richards and Kavanagh, all deal with allometric growth—that is to say, growth in which one part grows quicker than another, and the form therefore changes. Neither has anything very fresh to say on the matter. Medawar, in "Size, Shape and Age," probably has something fresh to say, since he combines a new mathematical approach with a new experimental technique. A tissue culture is placed in a medium in which Heaton's inhibitory factor is diffusing, so that the growth is slowed down on one side. He uses a mathematical method which is a development of one of D. Arcy Thompson's to represent the forms assumed and draws an analogy with the different growth rates of parts of the human body. But Medawar's ideas are still somewhat embryonic whereas the other four authors give useful summaries of a mass of careful work by themselves and others. Lotka gives a further development at one point of considerable mathematical elegance of his mathematical theory of population growth and decline.

He ends on a note of gloom regarding the future fall of population, which seems to neglect the fact that in many countries including both victors such as Britain and Czechoslovakia, and neutrals such as Sweden and Eire, the birth rate rose sharply during the war.

Dr. Berrill's paper on ascidian development is of interest because the ascidians are the animals most closely related to the vertebrates, which can develop from either a fertilized egg or a bud. A comparison of these two developments may have some bearing on human pathology. Dr. Wigglesworth's study of insect development is of wider interest, because he brings evidence that the parts of an insect are integrated not merely by hormones but by actual continuity between cells. For example if two bugs are joined by a capillary tube the hormones from one induce moulting in the other. But they moult simultaneously only if their skins are allowed to heal together. Thus he suggests that 'the epidermis is a chemical continuum upon which the cells are strung at intervals like beads upon a net'. In fact the organism is not a mere colony of cells but has some of the properties of a giant molecule.

The contribution which excited me most was Dr. Willmer's on tissue cultures. He suggests that cells should be classified not merely by their appearance and function in the body but by their behaviour under the standard conditions of tissue culture. Under such conditions some cells—for example neurones—will not grow. But the remainder revert to one of three types. The epitheliocyte forms a membrane and spreads over surfaces. The mechanocyte, which may be derived from muscle, bone, cartilage or connective tissue becomes a fibroblast, and forms a network in culture. The amoebocyte does not form a tissue. Further, the mechanocytes alone need embryo juice and are very sensitive to arsenic, the amoebocyte is phagocytic, the epitheliocytes tend to produce keratin, the mechanocytes collagen and so on. Dr. Willmer regards these three types as genera of cells, each with its own species including the carcinoma cell among the epitheliocytes and the sarcoma among the mechanocytes. I do not know if his views will be accepted. If so they are of the first importance. If not they will at least make a number of people think.

The whole volume is not only a tribute to a source of inspiration. It can be read with interest and profit by a wide circle. And very little of it will be too technical for the medical reader who wishes to keep in touch with the progress of thought concerning animal and human development.

J. B. S. HALDANE

SENIOR MENTAL DERANGEMENTS

Mental Disorders in Later Life. Edited by Oscar I. Kaplan. (Pp 426, illustrated \$5.00 or 30s.) California: Stanford University Press, London: Oxford University Press.

In psychiatry, as in other branches of medicine, the emphasis is rightly placed on the study of the disorders of childhood; nevertheless it may well be, as is stated in the preface to this book, that the mental disorders of older people have been grievously neglected. As a population we are growing older which makes it all the more important that we should do all we can to maintain bodily and mental health for as long as possible. Too often when an elderly person shows signs of mental derangement, even the expert jumps to the conclusion that he is suffering from an irreversible degeneration and that nothing can be done.

Among the seventeen essays by distinguished experts collected in this book perhaps the most important are those on the neuroses of later maturity, the involutional psychoses, and the toxic delirious reactions of old age, since they show that the patient suffering from these conditions, though he may be well advanced in years is not necessarily condemned to the inevitable deterioration of a dementia. It is pointed out that there is considerable similarity between the emotional stresses of the adolescent and of the ageing patient in that they are called upon to change a condition of security—in one case that of the protection of home and family and in the other a position of personal prestige and satisfaction—for one of insecurity. It is the loss of status whether of appearance, prowess or social and economic position which is so appalling to the aged, and it is very necessary for the individual and society to plan for old age so that the individual may remain useful, interested and respected for as long as is conceivably possible.

No doubt much could be done to prevent the evils of senility if over-exertion, over-eating and over-drinking, and various frustrations could be avoided, yet we know little enough about the causation of such an important condition as arteriosclerosis, or indeed of any of the degenerative processes. These essays cover the ground of senile mental derangements as thoroughly as can be expected in a book of 400 pages, and are both informative as to known facts and also stimulating in pointing out what an enormous amount of work remains to be done. Each essay is provided with a comprehensive bibliography, and an adequate index makes reference easy. This volume is certainly to be recommended, not only to psychiatrists but to all whose practice includes old people.

CARE OF THE NEWBORN

The New-born Infant. A Manual of Obstetrical Pediatrics. By Emerson L. Stone, M.D. Third edition, thoroughly revised. (Pp. 314. 16s. 6d.) London: Henry Kimpton.

The modern tendency to give the care of the newborn baby to the paediatrician has been resisted by some obstetricians, and it must be agreed that when the latter show keen interest in the baby their contributions to the subject are especially valuable. The third edition of *The New-born Infant*, by Prof. Emerson L. Stone, is a good illustration of this. It began as a course of lectures when the author was assisting Prof. Whitridge Williams at the Johns Hopkins, and now, in a complete revision, it provides a most useful and well-documented manual on the newborn. It is especially of value because it is essentially the outcome of long experience, and the author's practical outlook is well combined with his critical appraisal of other experts' publications. The section on intracranial birth injuries includes an account of subdural haematoma, but strangely omits consideration of cerebral oedema and of states short of gross haemorrhage. The terminology of jaundice in the newborn is also a little unusual, and in fact this disorder appears under diseases of the skin, though elsewhere there is a good summary of the story of the Rhesus factor. These few criticisms represent all the serious points of disagreement with standard teaching in this country that can be found, and it may therefore be concluded that Prof. Stone's work can be confidently recommended as embodying the modern views on the newborn as developed and held in the English-speaking world. It is a thoroughly good little book.

MILITARY PLASTIC SURGERY IN S. AFRICA

Brenthurst Papers. Edited by Jack Penn, M.B., Ch.B., F.R.C.S. Ed. Johannesburg: Witwatersrand University Press.

This small volume, privately circulated, is a collection of papers from the Brenthurst Military Hospital, which was unfortunately destroyed by fire at the end of 1944. Various members of the staff have contributed, and the editor is professor of plastic, maxillo-facial, and oral surgery in the University of Witwatersrand.

The papers mostly describe standard plastic procedures, with illustrative cases. The descriptions are unfortunately rather sketchy and lacking in detail, which makes them of little use to the beginner and incapable of fair criticism by the expert. One or two new ideas are interesting and appear sound. The Bienthurst clamp for the extra-oral fixation of fractures, where needed, differs from other methods in that the bone is not penetrated, although a small skin incision is needed. The acrylic mould used in the reconstruction of eye sockets is a definite advance. The paper on metacarpo-phalangeal joint deformity is also worthy of study.

It is a pity that the book was not more carefully put together, for there is no index, the pages are not properly numbered, and that irritating fault—the spelling mistake—is all too frequent.

The League of Nations has just issued a *Handbook of Infectious Diseases*, with notes on prophylaxis, serum treatment, and vaccination (London: George Allen and Unwin; 5s.). This compendium, of pocket size, is the fruit of the clinical and bacteriological experience of the directing staff of the Cantacuzène Institute, Bucarest. The work reviews infectious and parasitic diseases grouped according to their aetiological agents. It gives briefly in respect of each, first, a clinical description, the symptoms whereby it can be diagnosed, and the treatment; and, secondly, the channels of contagion and methods of prophylaxis.

Preparations and Appliances

PIPETTE FOR REPEATED INJECTIONS

Dr. M. A. GAYAR, senior casualty officer and anaesthetist, Warwick Hospital, writes:

The problem of multiple injections has for a long time remained unconsidered until the introduction of systemic penicillin therapy. Several articles have been published on this subject, demonstrating devices designed to overcome the necessity for repeated skin puncture, but only with regard to penicillin therapy. To desensitize a serum-sensitive patient for antitetanus serum or to give small repeated doses of adrenaline in an asthmatic attack is even more distressing, especially where the patient is a child.

I have constructed a pipette (see Fig. 1) which has proved invaluable for repeated injections. It is simple, convenient to

FIG. 1.—(1) Either hypodermic or intramuscular needle. (2) Tubing/needle adapter. (3) Rubber tubing, capacity exactly 1/2 ml. (4) Solid glass rod. (5) Screw clip adapter, one complete turn of which injects 0.1 ml.

use, easy to sterilize, and has been in constant use for the past 5 months for giving penicillin, A.T.S., and adrenaline with great satisfaction; it is particularly useful in treating children. It would also be useful in cases of eclampsia, tetanus, and status epilepticus, where repeated skin puncture for giving sedatives or serum would precipitate an attack of convulsions.

For desensitization, fill the pipette by plunging its needle through the cap of the serum bottle and screw down its screw clip to empty the rubber tubing and then unscrew again to fill it with A.T.S. Sterilize the skin in the usual way, insert the needle hypodermically, and fix the pipette to the skin with a piece of adhesive over the glass rod. The required dose of A.T.S. can be injected at intervals by turning the screw. If more than 1/2 ml. is required, unscrew clip with the pipette still *in situ* and inject more serum into the lumen of the rubber tube with a fine hypodermic needle.

For treating an asthmatic attack with adrenaline employ the same principle as above.

For systemic penicillin use an intramuscular needle for the pipette (instead of a hypodermic needle), and remove the screw clip. Fix the pipette preferably to the skin of the thigh (see Fig. 2) and inject

FIG. 2

the required dose every 3 hours into the lumen of the rubber tube with a fine hypodermic needle. After injection cover the pipette with a sterile piece of gauze or lint, fixed to the skin with a piece of adhesive or "elastoplast." It will be noticed that as the capacity of the rubber tube is 1/2 ml. the first dose should be 1/2 ml. more than is required for actual injection. Alternatively the glass rod, which has a mark to indicate 1/2 ml., may be pushed down the rubber tube, so as to reduce its capacity to any required extent; after the course of injections the glass rod can be pulled back to the mark.

It would be advisable to change the site of the pipette once every 4 days to avoid a sterile abscess developing, though it has been used on several occasions for more than 10 days in the same site without abscess formation or untoward complaint.

The pipette was made for me by Down Bros. Ltd., of 23, Park Hill Rise, Croydon, to whom I am grateful. My thanks are due to Dr. D. R. Rigg, medical superintendent, for permission to publish this article; to all consultants, their assistants, and registrars in whose wards the work was carried out; to Mr. B. R. Jones, the pharmacist, for his help in supplying the materials; and to all sisters and nurses for their co-operation.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 16 1946

THE HEALTH OF INDIA

India is headline news at the moment. She is claiming her right to independence from the British Empire. Her people are threatened with famine on an unprecedented scale. Faced with the necessity for meeting such immediate problems, there is a risk that fundamental reforms may be pushed on one side and forgotten. India is in dire need of health reform and of the conditions which make health possible. In 1943 the Government of India set up a predominantly Indian and non-official committee, under the chairmanship of Sir Joseph Bhore, to be known as the Health Survey and Development Committee, to survey the health services of the country and to advise on their better organization and development. This committee has just presented its report¹ in four volumes. Vol. I surveys the existing conditions. Vol. II in 532 pages covers recommendations for both a short- and a long-term plan. Vol. III contains appendices, and Vol. IV attempts to summarize the whole report in 90 pages. Those interested in India and in the fruitful development of human beings should read the first two volumes in their entirety. As the authors say "The term health, whether it is applied to the individual or the community, implies more than an absence of sickness and indicates a state of harmonious functioning of the body and mind in relation to man's physical and social environment, so as to enable him to enjoy life to the fullest possible extent to reach his maximum level of productive capacity." They recognize that reformed health services alone are not enough; they must be integrated with reforms in agriculture, education, and transport. "The elimination of unemployment, the provision of a living wage, improvement in agriculture and industrial production, the development of village roads and rural communications . . . are all so many facets of a single problem calling urgently for attention."

Some idea of the size and nature of this problem can best be given by figures. The death rate for the general population in 1937 was 22.4 per 1,000 inhabitants, and for infants under 1 year 162 per 1,000 live births. The total deaths under 10 years as a percentage of the total deaths at all ages was in 1935-9 48.5%, compared with 10.0% in England and Wales. About 200,000 women die every year from causes associated with pregnancy and childbearing, and probably about 4 million suffer from varying degrees of disability. The average number of deaths from cholera was 144,924 and from smallpox 30,932—both preventable diseases. There are approximately 2.5 million infective tuberculosis patients in the country, and the total number

of beds available for treatment is in the neighbourhood of 6,000; the number of doctors qualified for posts in tuberculosis institutions is 60 to 80. At least 100 million people suffer from malaria every year, and at least 2 million die each year either directly or indirectly as a result of malaria. The number of hospital beds available in British India for the treatment of general and special diseases is about 73,000, or about 0.24 bed per 1,000 population, as against 7.14 in England and Wales. There are to-day in India 47,000 doctors, some fully qualified, some with the licentiate training only—i.e., one doctor to 6,000 people. There are 7,000 nurses—i.e., one nurse to 43,000 people—750 health visitors, 5,000 midwives, 75 qualified pharmacologists, and 1,000 dentists.

Apart from active disease, the first essential of health is absent—namely, adequate nutrition. Undernutrition and malnutrition are widespread. The majority of the people live on diets lacking in calories, salts, vitamins, and protein. To-day they face absolute famine, but in the past pre-famine conditions have been general. In addition to general lowering of efficiency and resistance to disease, deficiency conditions are rampant. The simplest prerequisites of healthy living—adequate nutrition, housing, sanitation, and safe drinking-water—are lacking, except for certain privileged individuals living in the larger cities.

In making constructive plans to meet the grim situation revealed in the survey the members of the Bhore Committee have decided to accept the following principles: (1) that under the conditions existing in India medical services should be free to all and provided by a salaried service; (2) that in view of the complexity of modern medical practice the health services should ultimately provide all consultant, laboratory, and institutional facilities necessary for diagnosis and treatment; (3) the health programme must from the beginning lay special emphasis on preventive work, and on maintaining the closest links between preventive and curative medicine—"The doctor of the future should be a social physician protecting the people and guiding them to a healthier and happier life"; (4) care of the rural areas must be considered the most urgent need. The long-term programme looks to an organization in each Province under a Ministry of Health divided into district organizations each caring for 3,000,000 people; secondary units; and finally primary units, each of which would look after 25,000 people. The short-term programme follows somewhat similar lines but is less elaborate, largely owing to the shortage of trained personnel. It contemplates, however, a number of units concerned with both preventive and curative medicine for the people as a whole, together with special health services for mothers and children, school-children, and industrial workers, as well as for dealing with the more important diseases prevalent in India, such as malaria, tuberculosis, venereal disease, leprosy, and mental diseases.

It is reckoned that, at a minimum, by 1971 there should be 185,000 doctors, 740,000 nurses, 74,000 health visitors, 100,000 midwives, 62,000 pharmacists, and 92,500 dentists. Both long- and short-term schemes rightly concentrate upon the provision of medical aid to the rural areas. The primitive and squalid conditions of the villages associated with abject poverty cannot be imagined, but the few areas where

¹ Report of the Health Survey and Development Committee, Government of India Press, New Delhi, 1946.

experimental schemes have been in existence, like the district run by the, All-India Institute of Hygiene and Public Health and certain model schemes in the Punjab, show that, given encouragement and help, the Indian villager is eager and able to put into practice the essential laws of health. In the presence of good scientific medicine and education old customs and traditions lose their force. The indigenous systems of medicine flourish because there is no alternative. As a demonstration of what may be achieved by co-ordinated effort it is suggested that the Central Government should immediately implement the proposals for reconstruction not only of the health services but of education, agriculture, animal husbandry, and industry in Delhi Province, which for certain administrative reasons is particularly suitable for such an attempt. Associated with these plans for a complete medical service for the people are others concerned with the training of persons necessary to staff the service. The provision of such personnel is obviously the first essential to the success of any scheme, and here obviously is where Britain can and must help a courageous scheme of reconstruction by offering post-graduate training facilities to carefully chosen graduate students in all fields of the health services.

Sir John Megaw, whose lecture on the health of India was published last week, might claim that such schemes, far from helping India, may make her plight only more desperate. He sees her rising population as the root cause of the health problem. There will, he considers, always be a gap between the amount of food available and the number of mouths to be fed; therefore there will inevitably be malnutrition as the basis of ill-health unless something is done to restrict the growth of population. This he considers can be achieved only by changing the outlook on life of the people. The Bhore Committee recognizes that no programme of social reconstruction can afford to ignore the implications of the population problem. It realizes the difficulties inherent, particularly in a country with the varied religious beliefs of India, in achieving a reduction in the rate of additions to population, but it hopes that this may in time be achieved by raising the age of marriage for girls, improving the standard of living, and by intentional limitation of families. In the meantime their social instincts, as must those of all civilized people, prevent them from withholding reasonable health services for the nation for fear of their life-saving effect.

It is easy to criticize the schemes in the Bhore report as too elaborate and too ambitious. What matters is that a group of Indians and Englishmen representative of different parties and different beliefs have together reviewed the weighty problems involved and have together produced an agreed scheme, characterized by both vision and attention to practical detail, for the health development of India. The problem has been stated, in a dry analytical manner, of a vast nation short of food, short of sanitation, short of water, short of medical care. Men of good will from all parties in the State have hammered out a plan to build up a healthy nation. The future Government of India, whatever it may be, has been given a blue-print for her health services which it will do well to implement at the earliest possible opportunity. Health must stand outside politics. Its safeguarding should not wait upon constitution-making.

PENICILLIN IN BACTERIAL ENDOCARDITIS

Subacute bacterial endocarditis stands apart from all other infections due to the common cocci in its resistance to treatment. Since the earliest days of penicillin therapy this disease has figured as the last stronghold of streptococcal infection, on which an attack could be made only when an overwhelming force had been recruited. We have referred from time to time to the earlier moves in this campaign, and to the restrictions which have been placed on the use of penicillin for this purpose. The results in the first few groups of cases treated in the U.S.A.—usually with doses inadequate by present standards—were not altogether encouraging, and at a time when even a patient with staphylococcal septicaemia might not always be able to get penicillin its use for so problematic a benefit seemed unjustified. Moreover, the first pronounced success was achieved only by using quantities of penicillin which then appeared grossly extravagant, although they are now commonplace and have even been far surpassed. The protests which first greeted these attempts in the U.S.A. were extinguished by rapidly mounting production, and the treatment of subacute bacterial endocarditis with penicillin has now been in progress at many American centres for some two years. The development of penicillin therapy in this country has been hampered by greater scarcity of supplies, and it was not until the beginning of last year that a decision was taken to allot a certain quantity to the treatment of this disease. Its distribution and the manner of its use were entrusted to a committee of the Medical Research Council, whose first report will be found on the opening page of this *Journal*.

This report is a condensed statement by the secretary of the Penicillin Clinical Trials Committee, Prof. R. V. Christie, embodying the results obtained at 14 centres established by the committee. The series of cases so assembled is the largest yet to be published, and permits of statistical analysis in some detail. It deals with 147 patients, of whom 81 have been apparently cured—a satisfactory proportion which is likely to increase somewhat in the future when the lessons which have been learned during this investigation have been generally applied. The main object was to establish an optimum system of dosage, and by giving a constant total dose at different rates it was clearly shown that the first essential is prolonged treatment. Taking, then, the necessary period as 28 days, daily doses of different magnitude were compared. In assessing these results the important criterion is the relapse rate. A certain proportion of deaths during treatment owing to more or less mechanical accidents is inevitable: what matters is whether the infection is extinguished in patients who survive this period. Judged from this standpoint, a dose of 500,000 units a day is superior to lesser quantities; among 24 patients so treated the relapse rate was *nil*. The report also deals with policy and prognosis in re-treatment, and with the relation between prognosis and the degree of sensitivity of the infecting organism to penicillin. Although the single example of *Haemophilus* endocarditis in the series and two cases due to exceptionally resistant streptococci were frank failures, within limits not quite so wide as this

the coefficient of resistance of the organism did not appear to affect the results of treatment.

We also print a report dealing in more detail with the cases treated at one of these centres. G. E. S. Ward and his colleagues at the Middlesex Hospital have treated 18 patients, of whom only 1 failed to respond to treatment; 3 died in consequence of mechanical accidents, leaving 14 whose infection has been overcome, although 2 of these are threatened with heart failure. All these patients were given 480,000 units a day for 28 days by three-hourly intramuscular injection. Opinion is apparently divided on the relative merits—whether for the patient's comfort or for therapeutic efficiency—of such divided doses and continuous administration by intramuscular drip. It will be recalled that the original method of administration employed by Florey and his colleagues at Oxford was by continuous intravenous drip; this was abandoned in favour of spaced intramuscular injections owing to the frequency of venous thrombosis, due mainly to impurities in the penicillin then available. The continuous intramuscular drip is a compromise between these two methods which has given much satisfaction in some hands, although irregularities in the rate of flow have sometimes been troublesome. For the treatment of bacterial endocarditis Jessamine R. Goerner, A. J. Geiger, and Francis G. Blake¹ have reverted to the original method. Evidently the greater purity of the present-day penicillin has obviated its main drawback, and these authors claim for it freedom from trouble, convenience to the patient, and the regular maintenance of the desired level in the blood. They illustrate a group of three patients, two of them sitting up in chairs and one playing cards, all with delivery tubes splinted to their arms. Apart from any question of the patient's comfort, the respective merits of continuous and intermittent injection are still unsettled as regards their therapeutic effect: these authors claim that their own results strongly favour the continuous method. They treated 12 patients, employing a routine dose of 240,000 units a day for 3 or 4 weeks. The dose was increased and the treatment prolonged further if the initial response was unfavourable. Only one patient failed, for no ascertainable reason, to respond even to repeated courses; the remainder are all alive and well, in some cases after more than a year. A feature both of this report and of that from the Middlesex Hospital is the emphasis on eradicating foci of sepsis. The infection in subacute bacterial endocarditis is derived from the mouth, and when its actual point of origin is an apical abscess this focus should be eradicated in order to prevent recurrence. Numbers of extractions were found necessary for this reason, and were performed "under penicillin cover"—that is to say, penicillin was administered over a period of at least several days, during which the extraction was done. Heparin was used in none of the English cases and in only one of this American series, this being the single failure: here heparin was brought in when penicillin alone had failed, but without benefit.

These results, and others from the U.S.A. to which we have referred recently, establish the penicillin treatment of

bacterial endocarditis on a sure basis. While the ultimate prognosis still involves an element of uncertainty, it is clear that in a majority of cases the infection can be eradicated and the patient restored to normal health, except in so far as permanent valvular damage impairs this. Since this treatment will now presumably be given increasingly widely, it should perhaps be emphasized that the diagnosis must be beyond doubt before this arduous and costly proceeding is undertaken; one or preferably more unequivocal positive blood cultures are essential. In the treatment itself the prime necessity is to continue adequate dosage without any intermission for a month. It is a most reassuring feature of the extensive British series published to-day that relapse was most exceptional more than forty days after treatment had finished. If relapse does occur at an earlier stage a further full course may be undertaken with at least moderate prospects of success: 8 out of 26 such patients in this series finally recovered.

TOXICITY OF URANIUM

With the increasing interest in the development of atomic energy the toxicity of uranium becomes of the highest importance. In the U.S.A. nearly 70,000 people were employed over a period of three years to produce two atomic bombs. The secrecy surrounding these factories is complete, but we are led to believe that there have been no cases of serious poisoning. Uranium is radio-active, and this property has long been thought to be the cause of the high incidence of carcinoma of lung among the miners of Schneeberg and Joachimstal in Czechoslovakia. Fairhall,¹ reviewing the inorganic industrial hazards, pointed out that the metal could be detected by means of a sensitive Geiger-Mueller counter in amounts as small as 10⁻¹² grammes. He states that the metal is used to increase the hardness of steel, in colouring glass a fluorescent canary colour, and as the black oxide for red and black in the ceramic industry. It is used as a catalyst. Uranium oxide also has a new and important industrial application in connexion with the elimination of the effect of current surges in powerful projection lamps. Fairhall says that uranium and its salts are highly toxic, and that chronic nephritis and hepatic degeneration have occurred, but no reference, however, is made to its carcinogenic properties or its effects on haemopoiesis. It is likely to be many years before the full effects on these systems are known. Wiesner² has drawn attention to possible biological dangers from atomic fission, the results of which it may take even longer to discover.

From the U.S.A. Gustafson, Koletsky, and Free³ showed that dogs given uranyl nitrate intravenously developed severe tubular necrosis of the kidneys: anuria appeared on the fifth day, and the dogs died within a fortnight. The blood urea rose to 360 mg. per 100 ml. on the tenth day, the blood creatinine rose to 25.8 mg., and the serum chlorides fell to 61.2 milli-equivalents per litre. At necropsy a brown precipitate of uranium was found in the necrotic debris obstructing the lumens of the descending segments of the proximal convoluted tubules. Holman and Douglas⁴ made calibration curves of the alpha particle activity of standard dilutions of uranium in blood plasma, and thus made use

¹ *Physiol. Rev.*, 1945, 25, 152.

² *Lancet*, 1945, 1, 33.

³ *Arch. intern. Med.*, 1944, 74, 416.

⁴ *Proc. Soc. exp. Biol.*, N.Y., 1944, 57, 72.

of the natural radio-activity for tracer studies; they showed that in dogs given intravenous uranium radio-activity in the blood stream was minimal after four hours and in twenty-four hours had returned to normal levels; 65% of the uranium was passed in the urine in the same period. The dogs, however, still died unless they were also treated with sodium citrate. Gustafson and his colleagues, as well as Darnelly, Ross, Meroney, and Holman,⁵ confirmed that sodium citrate, given either orally or intravenously, protects the kidney against uranium poisoning; the latter authors showed that by the third week two-thirds of the damaged tubules were lined by newly formed flattened epithelium, and that nine months after the injection normal broad columnar epithelium lined the proximal convoluted tubules. Unfortunately, at present, there is no satisfactory explanation why sodium citrate protects against a lethal dose of uranium nitrate.

TOXICITY OF D.D.T.

D.D.T. is now available to the public and is being more and more widely used. At the same time further information is coming to hand about its toxicity to man and other vertebrates. The first fatal case of D.D.T. poisoning was recorded by Hill and Robinson⁶: a negro child aged 1 year drank about an ounce of 5% D.D.T. in crude kerosene. Atropine 1/400 gr. (0.16 mg.) was given and the stomach washed out about three hours later, but death from respiratory failure occurred at four hours. The lethal dose of D.D.T. was surprisingly low—apparently about 150 mg. per kg. Balaban,⁷ however, points out that the toxic effect of the kerosene carrier alone might have been quite considerable. An experimental study of D.D.T. intoxication in man is reported by Case.⁸ Two men lived in a small chamber painted with D.D.T. distemper and subsequently covered with a thin film of lubricating oil. Temperature and humidity were kept high, and the men, who wore short trunks only, had to sit so that a large area of skin was always in contact with the oily walls. Toxic effects were produced which were reflected in changes in the blood picture. Symptoms of tiredness and aching were experienced, and it is stated that several weeks passed before there was a return to normality. While it is clear that D.D.T. intoxication may result from severe exposures, it is difficult to know what reliance should be placed on the persistent subjective symptoms. Dangerfield,⁹ in a recent letter, suggests that the symptoms described by Wigglesworth¹⁰ were probably exaggerated by nervous anxiety. He records extensive experiments in which solutions and pastes of D.D.T. in acetone were applied to the hands of volunteers, who subsequently experienced no ill effects.

A study of possible hazards from the use of D.D.T. aerosols has been made by Neal and others¹¹ on a variety of test animals. They state that the aerosols were insecticidally efficient at air concentrations of 0.004 to 0.007 mg. D.D.T. per litre. In order to produce serious intoxication in the test animals they had to use concentrations of the order of 20 to 30 mg. D.D.T. per litre; so there seems to be a safety margin of 3,000 to 4,000 times the normal insecticidal dose of aerosols. Tests of the toxicity of aerosol concentrates and pathological examinations gave similar results to those summarized previously in this *Journal*.^{12 13} Small

and young animals were more susceptible than larger and older animals. Dogs were particularly resistant—an observation which conflicts with that of Hill and Robinson,⁶ in which two dogs died as a result of a single spray treatment of 5% D.D.T. in kerosene applied for demodex eczema.

The possible ill effect of D.D.T. on wild life has been widely discussed. The most likely vertebrates to suffer are fish. Emulsions or suspensions of D.D.T. above 0.1 part in a million are toxic to goldfish.^{14 15} During field experiments with mosquito larvicides containing D.D.T. Ginsbury¹⁴ observed that it had a harmful effect on black bass, catfish, and salt-water minnows. Eide and others¹⁵ showed that other cold-blooded aquatic life, such as frogs, snakes, crayfish, spiders, and insects, could be affected by D.D.T. suspensions, but during the trials warm-blooded animals got off scot-free. It was concluded, however, that fish and other vertebrates were not poisoned by dosage rates suitable for mosquito control.

SMALLPOX

Service men and women in large numbers are returning to this country by aeroplane and ship from places where variola major is endemic, and they or their kit may be infected. Many of them are so well vaccinated that should they develop the disease the constitutional symptoms may be so slight and the rash so modified and sparse as not to inconvenience them (the same is, of course, true of well-vaccinated persons who have not been out of the country); should they seek medical advice it is possible that a diagnosis of variola major may not be made in the absence of practically all the classical symptoms and signs of this disease. Two such cases in Hampstead Metropolitan Borough and Thurrock Urban District have given rise to localized outbreaks, and in both the diagnosis was made possible only by later events. Up to March 12 eleven subsequent cases (two fatal) have occurred; ten of these were probably direct contacts, and one (fatal) was infected by clothing. Both the fatal cases were haemorrhagic. In the circumstances it is important that all medical practitioners and hospital medical officers should bear smallpox in mind at the present time, and they are reminded that doubtful cases should be reported to the Medical Officer of Health, who will, if necessary, arrange for the gratuitous services of a consultant.

The King will open in London on Monday, June 17, an Empire Scientific Conference, arranged by the Royal Society, of which he is Patron. The conference will provide opportunities for men of science from the United Kingdom, most of the Dominions, India, and the Colonies, to discuss their problems in private. The subjects to be considered include nutrition and medical science. The Royal Society's conference will move to Cambridge for a week on June 22, and to Oxford for another week on June 29, returning to London on July 6. It is to be followed by the Commonwealth Scientific Official Conference in London from July 9 to 20, inclusive.

Dr. J. M. H. Campbell will deliver the Lumleian Lectures before the Royal College of Physicians of London on Tuesday, April 16, and Thursday, April 18, at 5 p.m. at the College, Pall Mall East; subject: "The Paroxysmal Tachycardias."

SOCIAL MEDICINE IN OLD AGE

BY

TREVOR H. HOWELL, M.R.C.P.E.

Late Deputy Physician and Surgeon, Royal Hospital, Chelsea

The number of elderly people in this country is now higher than it has ever been and is still increasing. According to the estimates in the Beveridge report, over 20% of the population will be either women over 60 or men over 65 by the year 1971, if present trends continue. It would seem advisable, therefore, to consider some of the social and medical problems which may result from this increase of old people. These same problems are present to-day, but in a far less acute form than they will soon develop. Now is the time to seek a solution.

Economic Aspects of Old Age

Until recently the shift in age of the population has been partly obscured by wartime conditions. Elderly men and women could earn good wages in domestic or industrial employment, which they would not do under normal circumstances. The war also gave them fresh interests in life, enabled them to meet new people, and widened their horizon. For the time being they felt themselves to be useful members of the community. But this is changing. As younger men and women are released from the Forces and factories older workers become less desirable. They become first unemployed, then unemployable; and an old man or woman without steady occupation grows infirm of body and mind more quickly than one who has something to do. It therefore seems possible that a number of dependent or helpless old folk will need to be looked after, either by their relatives or by public bodies. In the past disease has kept down the numbers of such people, but modern therapeutics is changing all that, as Molière might have said. The facilities which are available at the present time may not be adequate to meet the increased demands which will arise in the near future. It is therefore worth while considering the problem from the viewpoints of economic state and of social medicine, which are so closely related that they react on one another considerably.

It is evident that elderly people with some private means can enjoy the evening of their life without discomfort. They can afford to pay someone to do their domestic work, and are thus spared any undue physical strain or mental worry as a rule. Even the married couple drawing the old-age pension can carry on in their own home quite comfortably unless infirmity overtakes one of them. If the wife is active she can cope with an invalid husband, but otherwise the home is broken up for lack of anyone to do the domestic work. Similarly, an elderly widow or spinster can get along fairly well while she is healthy; but as she becomes more and more feeble, either in body or in mind, a choice has to be made eventually between appealing to relatives for help or entering an institution. Neither of these alternatives is pleasant at an age when prejudices are fixed and mental adaptation is difficult. The music-hall joke about the mother-in-law living with a young couple implies an obverse side which is rather pitiful. This combination of poverty and infirmity is one which causes a great deal of unhappiness in old people. The time is ripe for an attempt to prevent this as much as possible.

Domestic Help during Illness

In addition to these economic aspects of old age, certain other facets present themselves to the general practitioner and often cause him some worry. The first of these is related to the problems mentioned above. Many old women live alone and do their own housework. When they are taken ill domestic help is needed as well as medical and nursing attention. The district nurse will look after the patient, but there is nobody to take charge of the house. And it is not always desirable or convenient to send such people to hospital. Very often they do not wish to go there. Such patients may be taken ill suddenly and be unable to send for a doctor. It may be two or three days before a neighbour or some other visitor calls to see them, during which time anything might happen. Another problem is that of the single daughter who looks after an aged mother. If she becomes ill, then two patients, not one, need help and attention. Separation from the parent is so often a necessary part of the treatment of such a case. At times an old person

has some recurrent disorder, like a urinary infection, epileptiform attacks, and so on, being well one day but ill the next. These patients do not like the idea of going into hospital, nor do the hospital authorities like admitting them. Yet they often need more care and attention than is available at home. Another difficulty, most marked in country districts, is that of cases which need prolonged observation and investigation. It is not usual to get the highest "opinions" in the infirmaries which admit senile and chronic cases. Another point worthy of mention is the difficulty of getting any physiotherapy in many parts of the country. So much disease in old folk responds better to various forms of heat and electric treatment than to drugs alone. But the greatest obstacle of all is the lack of interest in geriatric medicine, and the general feeling that nothing can be done for old age.

Since these problems and others akin to them will probably become intensified in the future, it is as well to look at some methods of solving them. First would seem to come some sort of home help and supervision for elderly invalids, especially those who live alone. Next, it is important to stop overcrowding of the institutions for the aged. Thirdly, the medical facilities available should be improved. Finally, the differing types of senile patients must be sorted out into those who need general care, nursing in sick wards, or complete attention. Above all, it is essential to see that institutions for old people do not develop into soulless barracks. They must become pervaded by the spirit of kindness, sympathy, and humanity.

It is probably not feasible to increase the number of old persons who are employed in domestic or industrial work. But a great deal can be done for the elderly unemployed to keep them active, alert, and occupied. If such people were visited regularly by trained personnel, akin to the present health visitors, they could be helped, advised, kept interested in hobbies or various pursuits, and assisted in many ways. Such visitors would be most useful if they had access to doctors, district nurses, hospitals, and sources of domestic help. By helping to tide over bad times they would defer for several years the entry of many old folk into institutions. Thus elderly men and women could be independent and happy in their own homes as long as possible. This would do much to lessen the troubles and worries which afflict so many old people.

Homelike Institutions

When at last it became necessary for an elderly person to enter some institution, he (or she) would not always need complete nursing and attention. Once the domestic burden was removed it would be possible for the new inmate to look after himself to some extent, to do a little in the garden, to mend, and so on. Some privacy and a simple but useful occupation would preserve self-respect and go far to prevent further senile deterioration. It should not be necessary to limit freedom of movement or to enforce too rigid a time-table. Small apartments of the almshouse type, preferably without stairs, would be suitable for this type of person if domestic help and some nursing supervision were provided. A small community of this sort may be found at Pearson's Retreat, Worthing. Here old people live in two-roomed apartments with a resident nurse to keep an eye on them and to look after their health. It might be necessary to provide communal meals, and a cafeteria system would have much to commend it. If places like this were in being the larger institutions could be reserved for those who were really infirm, senile, and sick in body or mind. Only patients needing medical attention and nursing care would have to be admitted. Inmates could be segregated into those who were ill, those who were senile, those who were incontinent, and those suffering from senile dementia. In this way a sick old woman would not have her sleep disturbed by the shouts of the mentally deranged patients, nor would an alert but crippled old man be depressed by the sight of cases dying beside him.

These institutions should preferably be attached to a general hospital with proper facilities for all necessary investigations. The training of both medical students and nurses would benefit if they had experience of work among such senile and chronic cases. The post-mortem room would offer a great deal of material interesting to the pathologist, and there is no reason why valuable research should not be carried out in such hospitals. It would not be difficult to attain a high standard

of medicine in such a "chronic" institution if consultants and specialists were invited and encouraged to take part in the work there regularly. Medical activity would also give rise to a pleasanter atmosphere among both staff and patients. Old people are happier when they feel that an interest is being taken in their welfare and activities. They thrive on individual attention and dislike any mass treatment. Their own possessions, their own bed, their own seat at table—these mean much more to them than to younger persons. Even men who have spent much of their lives in the regular Army, and are used to a regimented existence, are happier and more amenable to reason when given some degree of privacy and personal rights. But how is this to be done? In apartments of the almshouse type this exists to some extent. In hospital wards for the sick personal freedom must be limited, of necessity, to allow the regular routine of work to be carried out. But, outside these two classes, a solution on the lines of the "bunks" in the long wards of the Royal Hospital, Chelsea, might be practicable. Here each old pensioner has a small cubicle containing his bed, chair, table, and locker. There is an aperture which he can curtain off, or shutter as he chooses, and a door which he can close. Thus he gets a sense of privacy and personal possession which helps to maintain his self-respect.

Freedom of movement, both within the building and to some extent outside it, should be allowed. Strict segregation of the sexes is unnecessary. It seems cruel, when they can no longer look after themselves, to separate couples who have lived together for many years of happy married life. Recreation of suitable kinds should be encouraged, games, gardening, and so on being favoured. If some community spirit can be roused and fostered, the well-being of all the inmates will flourish. Also, self-reliance will be preserved, and this will postpone the day when the old person becomes helpless and dependent on others for everything. Some care and thought will be needed for the naming of such institutions, in order to avoid a stigma derived from association with the workhouse infirmary, etc. Finally it must be stressed again that the personal attitude of the staff in these homes and infirmaries is the most important factor in making them happy and successful.

Conclusion

To conclude and summarize these remarks: it is urged that consideration should be given to the need for making happy the last years of poor and lonely old people. If they can be given some domestic help, together with supervision and nursing attention, while the public assistance infirmaries are allowed to become medically active centres with a truly humane atmosphere, then a great step forward will have been taken. Sympathy for the sorrows of old age is not enough: it is time to translate it into action.

MEDICAL AID TO CHINA

[FROM A CORRESPONDENT]

Early in 1939 the victory of Franco had resulted in the internment in France, under bad conditions, of a number of refugees. Among them were doctors of various nationalities who had served with the Republican army. At the same time China was in great need of medical help, and a committee—the Medical Aid to China Committee—was formed, mostly of medical men and women, and succeeded in rescuing some of these doctors, sending them fully equipped to China, and paying them a living wage. Readers of this *Journal* will perhaps remember that appeals were made in its columns. At the same time a Norwegian committee was working on the same lines, and altogether nineteen men were sent out. They settled down well, learnt the language, and did excellent work in conditions difficult and unhealthy. With the fall of Norway the English committee took on the care of the whole nineteen, and with increasing trouble in remitting money the responsibility became onerous. Then the United (now British United) Aid to China Fund was established and, though the committee retained its identity, its resources and collections were pooled with the Fund, which took over its responsibilities and, with its better organization, was able to help the men more effectively. With the defeat of Japan the problem of repatriation arose, for that was still the moral responsibility of the committee. This proved

almost insuperable, passages, visas, passports presenting endless obstacles, for the men comprised Poles, Czechs, Austrians, and Germans. Fortunately seven had been adopted by the American-Chinese Army in Burma, and when hostilities ceased the Americans shipped them to Europe and they reached their native lands.

One of the team had found employment for himself, but eleven still remained. Then came the news that U.N.R.R.A. had enrolled them in its organization, and better helpers could hardly be found. The wanderings of our colleagues seem to be coming to an end, and the committee has perhaps saved their lives, for if left in the concentration camp the overrunning of France would surely have been the end of them. So it was with some self-satisfaction that on Feb. 13 the committee held its final meeting. The members made a presentation to Dr. Mary Gilchrist, the honorary secretary, who had shouldered most of the work of all these troubled years. The British Aid to China organization was thanked for the help given when it was most needed, and it was hoped that it would continue to receive that support from the committee's old subscribers.

MEDICAL SOCIETY OF LONDON DINNER

The 166th anniversary dinner of the Medical Society of London was held at Claridge's Hotel on March 8 after an enforced interval of seven years. The President, Sir James Walton, took the chair and the company included Lord Moran, P.R.C.P.; Sir Alfred Webb-Johnson, P.R.C.S., Surg. Rear-Admiral Sir Gordon Gordon-Taylor, President of the Royal Society of Medicine; Air Vice-Marshal Sir William Tyrrell and Sir Stanford Cade, Major-Gen. W. Brooke Purdon, Sir Henry Tidy, Dr. R. A. Young, Dr. Anthony Feiling, Sir Russell Wilkinson, Sir Philip Manson-Bahr, Mr. Lionel Colledge, Dr. A. Hope Gosse, Dr. H. E. A. Boldero, Mr. Zachary Cope, Mr. J. Johnston Abraham (biographer of Lettsom, the founder), Mr. E. W. Riches; Dr. Horace Evans and Mr. A. Dickson Wright (joint honorary secretaries); and the editors of the *Lancet* and the *British Medical Journal*. After the loyal toasts had been honoured the health of the Society was proposed by the guest of honour, Sir Alan Herbert, M.P., in a witty speech. The presence of ladies for the first time in the long history of the Society lured him into Parliamentary digressions, though he proclaimed more than once that he would keep off politics. He said that doctors were the most deserving of the human race and he was all in favour of them; like authors, they were in effect one-man businesses and should be protected. He looked forward to the future of the medical profession with some misgiving and felt little hope that anything to help it would happen in Parliament, though he would do his best when the National Health Service Bill was debated. He advised doctors to be careful of his friend Aneurin Bevan, who was unscrupulous in his means though his ends might be splendid; they should use a long spoon when supping with him. He himself felt it was wrong of the Minister to let the doctors know in private that he was going to cut off their heads and at the same time demand that nothing of this should be said beforehand in public. Sir Alan ended with a word of personal affection for the London Hospital and for Sir James Walton. The President, in reply, said that in spite of the war the Medical Society of London had remained active, largely thanks to Dr. Hope Gosse, and had suffered a very small loss in net membership, though 76 members had died during the past seven years. Material damage had been small and was now repaired, and the library had returned intact to the house in Chandos Street. He believed that the medical profession could, and should, take a large part in shaping the future of the public health services—but in an advisory capacity, retaining the trust of the public, and (because it had no political bias) acquiring the trust of the Government. Doctors feared lay bureaucratic control and wanted to preserve that sense of individual responsibility from which the civil servant shrank. Medical and surgical advances were due to aggregation of small individual contributions by many men, who reported and discussed them at meetings of societies when knowledge was in the making. Sir James felt that there was a great opening for clinical observations, especially by general practitioners. "By such means in our short lives we can attain immortality."

Nova et Vetera

ISLAM AND MEDICINE

With the object in view of showing that the end of the war affords an excellent opportunity for international co-operation and that in the organization of peace the Islamic world is likely to be a strong stabilizing factor, H H the Aga Khan and Dr Zakī Alī have written a survey of the fundamentals of Islam.¹ The greater part of this small book is devoted to proving how Islam had always encouraged the pursuit of medical science. This remarkable movement began in the eighth century and for the next 500 years the Muslims alone, following the precepts of the Koran, played a vital part in the evolution of humanity. They resuscitated Greek medicine by translating Galen's *Anatomy*. Hunayn ibn Ishaq was the author of an original work on eye diseases, and Abul Qasim, who wrote a medical encyclopaedia of thirty volumes, was credited with being an outstanding oral surgeon.

To early Arab chemists Europe owes its knowledge of corrosive sublimate, arsenic acid, silver nitrate, and many other preparations. They also investigated the existence of impalpable air-borne bodies. To them Europe owes the discovery of alcohol, even organotherapy was not unknown to them. With regard to physiology Ala ad Din (A.D. 1210-1288) described the pulmonary circulation, three centuries before Michel Servet. Perhaps the most illustrious investigator the East has ever produced was Avicenna, born near Bokhara in A.D. 980. He was the author of a textbook which included all the branches then known to medical science and which remained the chief medical classic for 600 years. He systematized psychology and recognized the value of psychotherapy. In helminthology he brought *Dracuncula medinensis* and *Ankylostoma* to notice, and differentiated between gonorrhoea and syphilis. In the domain of surgery Avicenna described tracheotomy, as also symptoms of pyloric stenosis and gastric ulcer. He wrote a remarkable dissertation on diseases of the liver and gall bladder. Among other Muslim scientists mention is made of Alī al Hussan, who made researches in optics with special reference to refraction.

There were women physicians in the East and in Muslim Spain, who graduated after long and practical courses in obstetrics and gynaecology. The foundation of well-equipped hospitals was a striking feature of Muslim civilization. Clinics, rooms, lecture halls, and medical libraries were provided. After students passed their examinations a diploma was given, so that the practice of the profession was confined to those who had undergone proper training.

Dr Zakī Alī's studies are concerned with the period from the ninth to the end of the fourteenth centuries, and in his documented story he has effectively shown the debt we owe to the glorious period of Muslim medical renaissance, which gave a strong impetus to Europe and led to a fruitful quickening of the spirit of scientific investigation in the West. It was an era which paved the way to modern civilization.

SIR THOMAS ELYOT (? 1490-1546)

On March 20, 400 years ago, there died a disappointed man, one of the more remarkable personalities in English medicine. His dreams had faded and his ambitions had turned to naught. The figure of Sir Thomas Elyot (his likeness is preserved in Holbein's drawing at Windsor) strangely stirs the imagination. Yet with the passage of the centuries we drift increasingly away from the actual man. Traditionally M.D. of Oxford. Traditionally the first medical man to receive a knighthood. A classical scholar who provoked the vociferous wrath of the medical profession when in 1534 he published in English a popular guide to medicine, *The Castel of Health*. This, incidentally, is a fascinating and touching autobiography, for it reveals the many diseases which plagued its author for so many years. His "Boke named the Governour" (1531) is described as the first English treatise on ethics. Though Sir Thomas Elyot served on two occasions as ambassador to the Court of the Emperor Charles V, it would be an extravagance to style him truant from medicine, having regard to the mystery which cloaks his medical career.

Reports of Societies

INFECTIOUS DISEASE CONTROL IN U.S.A.

At a meeting of the Fevers Group of the Society of Medical Officers of Health on Feb. 1, with Dr M. MITMAN in the chair, Dr ROBERT CRUICKSHANK, Director of the Central Laboratory of the Public Health Laboratory Service, talked on his "Impressions on the Control of Infectious Diseases in America."

Dr. Cruickshank remarked on the preoccupation in America with the infective neuropathies, such as the various forms of encephalitis and poliomyelitis. Rabies was a common infection among dogs and rabies vaccine was used extensively, although there was some doubt about its prophylactic value. Team work was usual in research in the laboratory, in the hospital, and in the field.

Diarrhoea and Dysentery

In the south western States of the U.S.A. the death rate from diarrhoeal diseases was high, for example, the annual figure for San Antonio, Texas, was 200 deaths per 100,000 population. The bulk of these were due to infections with the dysentery and *Salmonella* organisms, as in Britain many cases of acute diarrhoea were not reported to the health authorities. He gave an account of the epidemiological studies of Hardy and Watt based on some 1,600 cases of diarrhoea and examinations from 850 households totalling some 8,000 faecal cultures. Infection was most prevalent among children aged 1 to 9 years and most severe in children under 2 years of age. In older children about one-half of those infected showed clinical signs. In adults the ratio was 1 in 4 or 5. In a survey of 380 cases which yielded positive stool cultures less than 10% had diarrhoea, one-quarter were convalescent carriers and the rest were healthy contact carriers. The infection in America was rarely water- or milk-borne. Food borne outbreaks occurred in institutions; flies were not, apparently, important vectors, in most instances spread of infection was direct, person to person, facilitated by low standards of personal hygiene.

Sulphadiazine was used extensively and successfully for Flexner infections, in Sonne infections both soluble and in soluble sulphonamides were less successful. Sulphadiazine has also been used prophylactically for the control of dysentery in institutions but there was a danger of establishing drug fast strains. Streptomycin had produced rapid clinical and bacteriological cure in cases and carriers infected with sulphonamide resistant Flexner bacilli.

There was considerable interest in methods for improving food and restaurant hygiene, and Dr Cruickshank referred to the main faults and the ways in which they were being corrected. Education of the food handler was a most important factor in the control of infection.

Gastro-enteritis did not seem to be such a serious problem as it is in this country. Neonatal diarrhoea with a mortality of over 30% was attracting a good deal of attention. A virus had been isolated from infants suffering from stomatitis and diarrhoea, but the clinical course of this disease was unlike the gastro-enteritis prevalent in this country.

Respiratory Infections

Acute respiratory infections could be classified in two groups: (A) Those not controllable by prophylactic vaccination. (1) upper respiratory infections, including the common cold, catarrh fever, and primary atypical pneumonia, (2) measles, mumps and chicken pox, and (3) streptococcal infections. (B) Those in which artificial immunization gave reasonable hope of control: diphtheria and smallpox, probably pertussis, and possibly in fluenza and pneumococcal pneumonia.

Attempts were being made to separate out the hotch potch of upper respiratory infections and to control their spread in hospitals, particularly by the use of barriers of ultra-violet light. In schools ultra violet light had given some success in controlling the spread of the common childhood fevers, such as measles, mumps, and chicken pox. Progress was being made in the practical application of aural antiseptics.

Streptococcal infections had been very troublesome in Army training camps and were particularly common in New England.

and in the uplands of the Western States. They were followed by a high incidence of rheumatic fever. Recent work had suggested that heavy nasal carriers were important reservoirs for the spread of streptococcal infections, and as they might show no obvious stigmata of infection these carriers should be sought out by routine swabbing. Oiling of floors and bed-linen had given good results in the control of streptococcal infection.

Controlled field trials of vaccine action against pertussis were going on in a number of States, and good results were being obtained with three spaced doses of plain or alum-precipitated pertussis vaccine. Antibody tests and agglutinin skin reactions were being used as indices of the immunity produced by pertussis antigen. A mouse test had recently been introduced which might prove very useful in assessing the relative antigenic potency of different pertussis vaccines.

General Discussion

Dr. HARRIES (L.C.C.) asked about the present position of gamma globulin in measles treatment and prophylaxis in America. Dr. Cruickshank replied that gamma globulin was too depressant to be given intravenously for the treatment of measles; its value in measles prophylaxis had been in line with experience here. It had been confirmed that prophylactic gamma globulin would prevent infective hepatitis.

Dr. W. GUNN (L.C.C.) asked the lecturer about streptomycin. In addition to information about its pharmacology, Dr. Cruickshank gave details illustrating the valuable therapeutic properties of streptomycin in influenzal meningitis. It has also given promising results in experimental tuberculosis, and in certain human cases of progressive tuberculosis. American supplies were still under Government control and the cost of production was very high, but a number of firms were now making streptomycin on a commercial scale and there were indications that, in addition to its possible use in tuberculosis, it would act as a complementary chemotherapeutic substance to penicillin.

Dr. M. MITMAN said the space allowed in catering establishments for the preparation of food was usually totally inadequate; he had good authority for stating that it should comprise one-third of the total floor space. Architects were interested chiefly in designing the restaurant, lounges, and bars, and few of them were competent to plan kitchens. The Americans were ahead of us in providing refrigerator space. Incubation after food contamination was an important factor in food-poisoning, and refrigeration prevented it. Dorling's case (*Lancet*, 1942, 1, 382) was an excellent example of such incubation. A woman of 61 living alone opened a tin of wholesome soup and in so doing contaminated it with staphylococci from her septic thumb; she consumed half the soup without ill effect and left the rest in her warm kitchen for seven days. She then rewarmed the remaining half and consumed it; within three hours she was violently ill with food-poisoning, and within twenty-four hours she was dead.

Nasal carriers were important disseminators of infection, not only of diphtheria bacilli and streptococci, but also of pathogenic staphylococci. From his bacteriological examinations of the nose in septic cutaneous conditions, including furunculosis, he was satisfied that many of the skin lesions were auto-infections from the nose and were not attributable to the general health of the patient. The carrying of staphylococci in the nose was common, and the frequency with which the hands of normal people straved to their noses was surprising. For the treatment of intestinal infections he preferred to combine an unabsorbable sulphonamide—sulphasuxidine—with an absorbable one, such as sulphamezathine or sulphadiazine.

PSYCHIATRIC PROBLEMS OF REPATRIATED PRISONERS

A meeting of the Section of Psychiatry of the Royal Society of Medicine on Feb. 12, with Dr. G. W. B. JAMES in the chair, was devoted to some psychiatric problems of repatriated prisoners of war.

Dr. MAXWELL JONES gave an account of work, in collaboration with Dr. Tanner, at the special unit at Dartford, where 829 prisoners of war had been treated. A special investigation was carried out between June and September, 1945, every fifth admission—100 patients in all—being studied according to a

rather elaborate standard formula. Family and personal history, home atmosphere, social circumstances, schooling and work record, marriage, range of interests, personality type, intelligence, and physique were all taken into account. An assessment was made of the stresses to which the individual was subject before his Army service and of his reactions thereto. He was examined in relation to his Army adjustment, domestic worries, experiences in prisoner-of-war camps, and his re-adjustment on returning to his home and unit. The results of the investigation brought out the normality of the group, which was the more striking to the investigators who had been accustomed to deal with a neurotic population. Of recent severe stresses, 58% mentioned poor food, 30% stress on active service, 26% Allied bombing while in prison camp, and 24% conditions on the marches at the beginning and end of captivity; 88% stated that sex was no real problem; 82% that enemy propaganda had no effect; and 58% that they had not been subjected to any unreasonable degree of punishment or cruelty.

The most common symptoms encountered were breathlessness, tremor, a feeling of "not belonging," shyness in the presence of women, resentment towards the Army, fatigability, and lessened tolerance. The low-rated symptoms were also of interest: fear of impotence or actual impotence and of loss of family affection, battle dreams, weeping, pain on breathing, and diarrhoea and vomiting. In no single case was hysteria a major manifestation. While it was premature to draw final conclusions, all the evidence pointed in one direction—namely, that these patients, although they differed from the normal population, were not neurotic. In response to standard exercises their oxygen intake was similar to that of normal controls, pulse response was normal, and the results of treatment were rapid.

In the treatment programme at Dartford particular attention was paid to the resolution of social difficulties. The unit was fortunate in obtaining the co-operation of between forty and fifty local employers, ranging from small family businesses to large factories. The advantages of infiltration into a normal population were obvious. Various group activities, such as educational and entertainment programmes, were undertaken. Out of the 829 patients, 107 resided in and around London, and it was arranged that these should be followed up. To date 56 patients who had been discharged from hospital for three months or more had been visited, and a relative had been interviewed in every case. Only 4 men had done no work whatever, and 16 had taken more than eight weeks' rest before starting work; others started work almost immediately after leaving hospital. The average number of weeks worked in this group was nearly 13, and the average number of days off work on account of illness was 6, this figure having been increased by a slight influenza epidemic. Of the patients 20 had sought medical advice for nervous symptoms; 8 stated that they were completely symptom-free. In 47 cases the relative said that they had been greatly improved by hospital treatment. In 51 cases no change of employment had occurred; only 4 were in Government training schemes. In the unit the factors most beneficial, according to the patients, were the work therapy, the general social organization, and the quietness of the place. There was a resident disablement rehabilitation officer, who had been invaluable in helping those discharged.

Work of Civil Resettlement Units

Lieut.-Col. A. T. M. WILSON said that in 1941 attention began to be directed to this problem, and more recently units had been set up for dealing with repatriated prisoners of war. The men who went to these civil resettlement units, as they were called, did so as volunteers, and the degree of collaboration was more than had been anticipated. Had it not been forthcoming it would have been impossible to have overcome the suspicion of the men concerning the Army and its intentions. Although ex-prisoners of war had certain special difficulties, their problems were not greatly different from those of other repatriated Service men. The resumption of social relations, particularly within the family, made severe demands not only on the returning father but on his wife and children, who had problems of their own. Resettlement was a two-way affair, calling for mutual adjustments, whether considered in terms of family, place of work, or community as a whole.

He described the staff of a civil resettlement unit, with its specialist and vocational officers, Ministry of Labour and Red

Cross liaison officers professional women social workers, and others all helping the men to replace the control of military life by control suitable to civil conditions. No man was ordered to see anyone. When men were backward in making use of facilities it was regarded as a psychiatric problem. As yet no adequate information was available as to the permanent results of four or five weeks spent in such a centre but such information as could be gathered from social agencies, the Ministry of Labour employers and the men themselves and their families was encouraging. The men had realized that the Army had taken well informed social action in relation to their problem.

In the course of some further discussion a number of officers attached to civil resettlement units contributed their experiences. Major DOYLE the first psychiatrist to be appointed to a civil resettlement unit said that the most vexing problem was the small non cooperative group who were flagrantly antisocial and with regard to whom it seemed that expulsion was the only solution. This group was tackled by individual interviews and collective discussions. The men were told that although there was no punishment in the unit others were affected by their behaviour and that they were up against their community. This approach was effective, and one by one they gave an assurance that there would be no further trouble and the rest of the unit became not only more tolerant but even protective towards this neurotic group. The demand for psychiatric help in the unit rose from 5% of the cases at the beginning to 60% after three or four months. Major KILNER also said that the requests to see the psychiatrist were increasing. Every man consulting the psychiatrist was seen once or twice, the nature of his symptoms was explained to him and he was made to feel that his individuality was respected. "Therapeutic discussions" were held every week the themes selected by the group itself, and the psychiatrist, once the discussion was in full swing, receded into the background choosing the right moment for explanation and interpretation. The therapeutic side of the civil resettlement unit was represented not only by the psychiatrist but by the vocational and other officers. Brig BARBER described the arrangements for the repatriation of prisoners from Germany. The thing which had struck the officers in charge he said, was the extent to which the recently repatriated prisoner resembled the institutional child newly let loose on the outside world. Many had neurotic symptoms but gross phenomena were extremely rare.

A medical officer of one of the European Allied armies who had been in a prisoner-of-war camp said that the investigation of a sample of 250 cases had shown that the incidence of neurosis rose with length of captivity and jumped significantly between the second and third years. After two years there seemed to come a breaking point in the prisoner of war's power of adaptation. Chronic anxiety states increased relatively as well as absolutely with length of captivity. The most marked symptoms were headache, loss of power of concentration, and insomnia. Among the anxiety states, however there was an absence in his group of "barbed wire phobia" and the four cases of claustrophobia did not arise out of the incarceration. There was no instance of fear of impotence or sterility.

The PRESIDENT said that not only in prisoners of war but in fighting men generally the critical period was after two years.

NEONATAL INFECTIONS

At a meeting of the Section of Disease in Children at the Royal Society of Medicine on Feb 22 Prof NORMAN CAPON presiding the subject of discussion was neonatal infections.

Dr BERYL CORNER gave an analysis of infections among 6500 infants consecutive live births in two maternity units in Bristol. The infections included the smallest manifestations such as a spot on the skin. In one of the hospitals with just over fifty beds devoted entirely to maternity work the number of infants who showed some infection during the period under review was 869 or 25.3%. More than one infection—for example conjunctivitis and thrush—was shown in 83 and more than two infections in 8. There were three deaths, all from bronchopneumonia. The number of superficial skin lesions, cases with only a single lesion being included, was 198, eye

infections numbered 451, among which only 89 occurred during the first five days of life. In the second hospital the number of infected infants was 949, or 29.7%. More than one infection was shown by 129, and more than two infections by 33. Here deaths from infection—bronchopneumonia or gastro-enteritis—numbered 12. Eye infections totalled 563 and minor infections 61, some of these being severe enough to cause constitutional symptoms.

From these figures, said Dr CORNER, it was obvious that prevention of infection was a major problem in a maternity department. In the first hospital which had rather better figures, a serious effort was made three or four years ago to reduce infant infections particularly those of the skin. As long as pustules on a newborn infant's skin were dismissed lightly as a few septic spots and were not treated with the importance they deserved so long would serious staphylococcal infections arise in the nursery. The importance of apparently trivial infections could best be brought home to the nursing staff by keeping careful records.

It was important to devote attention to the kind of nursing staff required for the care of the newborn baby in hospital. The idea was tenaciously held that mother and baby were an inseparable unit and that the same nurse should care for both. That was the ideal in the days of private domiciliary midwifery but in these days of large-scale institutional midwifery with the 48 hour working week for nurses, and allowance for the large number of lectures to be attended by the pupil midwife, it was an ideal which could not be reached. In the second of her hospitals which was a teaching hospital the nurses spent only 40 hours a week attending their patients which meant that each mother and child must be attended by 4.15 nurses. The most practical solution to the problem was the nursing of the baby by a completely separate nursing staff. This had the advantages that the nurses' whole attention was focused on the baby and minor lesions were readily observed that the baby need never be left alone in the nursery that the baby's routine was undisturbed by maternal emergencies that the carrying of infection from mothers to babies was largely eliminated, and that all types of nurses apart from the midwife or pupil midwife could be used for routine nursery work.

In the treatment of infection barrier nursing was the first point. This was carried out not only for infants actually infected but for infants whose mothers had an infection. The nursery sister should be given power to start treating small lesions as soon as she saw them. Cases of pemphigus had been arrested because the nursing staff had been allowed to start treating the first few spots they had seen. For application to skin lesions 5% sulphathiazole in glycerine had been used at three hourly intervals, and in the majority of cases this would clear up septic spots in two, three, or four days. Penicillin cream, used in 33 more serious cases, seemed to have an advantage. Twelve cases of pneumonia had been treated with penicillin, with three deaths, all in premature infants. She urged that paediatricians should concentrate on improvements in nursing routine and technique in order to reduce the still unduly high neonatal morbidity.

The Ophthalmic Aspect

Prof ARNOLD SORSBY dwelt upon the importance of the ophthalmic aspect in sepsis in newborn children. Most of these infections of the eye developed after five or six days of life. That did not fit in with the classical conception of ophthalmia neonatorum in the newborn. One of the difficulties was a merely verbal one. The unfortunate term "sticky eye" represented the line of demarcation between the normal eye and ophthalmia neonatorum—it meant the slightly irritated or inflamed eye. The rate of blindness among school-children went down from 36.4 per 100 000 in 1923 to 26 in 1933 and 20 in 1943. In 1922 37% of all blind children were blind as the result of congenital anomalies of the eye, twenty years later this proportion had increased to 67% meaning, of course, not an actual increase in congenital anomalies but a relative decline in infective conditions as the cause of blindness. It would be a mistake to assume that these congenital anomalies were all genetic affections; at least a quarter of them were due to a transmitted infection like congenital syphilis. It was also well known that German measles in the mother was responsible for a certain amount of

blindness in the children, producing congenital cataract and extensive fundus lesions. The incidence of blindness and impaired vision resulting from ophthalmia neonatorum had gone down markedly during the last twenty years, but there was no evidence of any reduction in the amount of ophthalmia neonatorum itself. What had happened was that as a result of intensive effort the complications of ophthalmia neonatorum had been brought under control. The most significant of the measures was notification. In some countries silver nitrate prophylaxis was compulsory. In Scotland, while not exactly compulsory, it was very widely carried out. In England and Wales it was carried out in some places and in others ignored. There was no real evidence that instillation of a drop of antiseptic prevented the onset of ophthalmia neonatorum. The complications of ophthalmia neonatorum had been steadily declining for many years before the advent of silver nitrate; silver nitrate and penicillin had accelerated what was already occurring. The value of sulphonamides was, of course, undoubted, and they should be used as a routine measure, save in the specialized units where penicillin could be used. His experience of penicillin in ophthalmia neonatorum extended to 150 cases. It must be used in relatively strong concentration and with great frequency. It was easy enough to get a cure with penicillin, but no one yet could say how it could be used in a simple and effective method.

Nursing Routine

Dr. HELEN MACKAY was doubtful about the wisdom of the policy of nursing the babies apart from their mothers. It was important to guard the babies against maternal infection, but it was also important to teach the mothers to tend their babies before they went out of the maternity home, also to get unmotherly mothers interested in their babies as quickly as possible. The balance of advantage might be to keep the baby with the mother. Dr. C. E. FIELD said that about a year ago in her hospital there was a small epidemic of skin infection in one nursery, and the prophylactic bathing of the babies with penicillin cream was tried and gave good results as compared with controls. The PRESIDENT said that babies were bathed too often. One well-known paediatrician insisted that the baby should be bathed once at birth, and then not again until the cord came away, and that procedure had resulted in a material reduction of infections.

Dr. CORNER, in reply, said that the ideal thing was to nurse the baby with the mother if the latter was fit, but so many of the mothers came into hospital with all kinds of infections, and the records of her hospital showed definitely that a little crop of infant infections coincided with infections of the same kind in mothers who were being nursed in the same wing. As for bathing, it was the practice in her hospital to bathe the babies at birth and then on the fourth day. If the cord was not rated they were not actually immersed. After this they were bathed every day. It was possible that the bathing took place too often, but the routine of bathing—the complete undressing of the infant—was a means of drawing attention to any lesion that might otherwise remain undisclosed.

A meeting of the Medical Society of the L.C.C. Service was held at the Maudsley Hospital, Denmark Hill, S.E., on Feb. 7, when 115 members were present. Members of the staff of Maudsley Hospital demonstrated the methods and appliances used in present-day psychology, and showed films of "The Physical Treatment of Neurotic States" and "Neuropsychiatry," and demonstrated cases of prefrontal leucotomy, anxiety state, G.P.I. treated with penicillin, and exophthalmic ophthalmoplegia.

The Washington Institute of Medicine (1720 M Street, N.W., Washington, D.C.) announce the following publication of two new periodicals. The *Quarterly Review of Psychiatry and Neurology*, with Prof. Winfred Overholser, M.D., as editor-in-chief, is to appear in January, April, July, and October of each year. The *Quarterly Review of Urology*, with Dr. Hugh J. Jewett, of Johns Hopkins University, as editor-in-chief, is designed to present concisely not only all progress in the field of urology but also important developments in other branches of medicine which are, or may become, of urological significance. It is to be published in March, June, September, and December. The annual subscription to each review is \$9.00.

Correspondence

Making Meaning Clear

SIR,—One of the advances in modern therapeutics has been the introduction of methods for determining the concentration of drugs in the blood stream. Such methods greatly accelerated the application of the sulphonamides and the new antimalarials. Unfortunately, in the case of salicylates and penicillin the established convention of reporting biochemical data in terms of 100 ml. of blood has been disregarded, and results are given in terms of microgrammes or decimals of units per ml. This is all very confusing, for most of us would find it much easier to remember the therapeutic range of penicillin as 4 to 20 units per 100 ml. than as 0.04 to 0.2 unit per ml. Part of the art of writing is to remove unnecessary obstacles from the way of the reader, and it is therefore to be hoped that editors will persuade contributors to revert to the normal custom.—I am, etc.,

Oxford.

L. J. WITTS.

Words and Clear Thinking

SIR,—I feel it is time Dr. Geoffrey Bourne's words under this heading (*Journal*, Oct. 21, 1944, p. 543) were reiterated: "Clear thinking is largely determined by clear expression. Those who misuse words are enemies to science." He enumerates the reasons for abandoning the terms "hyperglycaemic coma" and "hypoglycaemic coma." Others have joined him: "Why hyperbaric and hypobaric?" asks Lieut.-Col. H. Williamson (Sept. 15, 1945), recommending the safer synonyms "heavy" and "light." Your own leading article, "Drugs and the Doctor" (Oct. 21, 1944), describes proprietary names of drugs as "a problem," instancing sulphanilamide, offered under fifty-odd names at the last time of recording. Dr. A. Piney (Dec. 15, 1945) looks forward to a meeting of haematologists to clarify "the unwieldy terminology of their subject."

After reading these heartening contributions it is disappointing to see Dr. W. J. Gardner (Feb. 9, 1946) disparage the "myringotomy or paracentesis?" discussion so well introduced by Mr. T. B. Jobson (Jan. 5). He may be disgusted at one of the words later suggested, but his contempt of this type of correspondence is mischievous if our vocabulary is to undergo any improvement. It is also very disturbing to see your reviewer of the new supplement to the *B.P.C.* (Dec. 15, 1945) waiting for the day, which he thinks "will surely come," when that impartial publication shall burden its pages with a multitude of terms invented at random by private firms.

Medical terminology invites reform in several directions. I believe it was H. G. Wells who said (long ago) that scientists have yet to learn what every novelist knows—that is, that different characters in the same plot should not have similar names. Yet the "hypers" and "hypos," "ads" and "abs" remain, to our constant confusion and danger. The annoyance is worse when we see all the contrasting terms the drug houses can produce for a single substance.

A third obstacle to clear thinking, the least necessary of all, arises when we mix the meaning of such good words as we possess. An example has appeared in your columns at the time of writing. Dr. Gaskell (Feb. 16) defends a previous letter by quoting a well-known textbook in which the dilute plasma at the top of the E.S.R. tube is called "serum" fourteen times in three pages. This, he says, is good enough for him. Surely, at a time when perhaps hundreds of bottles of dried plasma and dried serum are issued weekly by the transfusion services, it would be more reasonable to recognize the difference between these substances and refrain from using their names interchangeably. It is not enough that the authors of the textbook are clear in their own minds about the matter, or that readers "know what they mean." They have confused Dr. Gaskell and will confuse others. (Dr. Gaskell will see his other troubles explained in an article such as that in the *Journal* of Sept. 5, 1942, p. 278.)—I am, etc.,

Brocket Hall Hospital, Welwyn.

T. C. BEARD.

Fractured Patella

SIR.—Mr. R. Brooke (Feb. 16, p. 231) has not convinced me that the patella is a useless bone which may be sacrificed with impunity. I believe that it serves a useful purpose and that when it is broken it should be mended and so far as possible restored to its normal condition. As Sir Max Page (March 2, p. 329) has pointed out, loss of the patella gives an ugly flattened knee, while the functional results of excision are often very imperfect.

On the other hand, it must be admitted that the results of suture are not always perfect, and the reason is that suture or "wiring" alone, however competently done, is a mechanically inefficient method of uniting a transverse fracture. In fact, it is bad carpentry. Frequently the result looks perfect on the operating table, but the x-ray photographs taken a few days later show tilting of the fragments and partial separation of the fracture surfaces. This applies both to the transverse fracture of the patella and to the common fracture of the olecranon.

For some years I have used a combination of pegging and wiring for these fractures. The fracture surfaces are cleaned and fitted most accurately together. They are firmly held together while first a drill and then a bone peg is passed into the long axis of the bone. A malleable stainless-steel wire is then passed transversely through the fragments above and below the fracture, and it is drawn tight and twisted in the usual way. The peg prevents any tilting of the fragments, while the wire holds them together.

In the case of the olecranon a long central screw is good carpentry if it will hold. But neither a screw nor a peg can be relied on to hold in the soft cancellous tissue of the shaft of the ulna, so that combined pegging and wiring is better.—I am, etc.,

London, W 1.

A. S. BLUNDELL BANKART.

Suprapubic Drainage of the Bladder

SIR.—Mr. E. W. Sheaf (March 2, p. 331) is wise to draw attention to the dangers of suprapubic cystostomy by a blind operation. An experienced surgeon can make the same mistake as Mr. Sheaf's "competent house-surgeon," for how will he be sure of avoiding the peritoneum in the region of the upper half of the anterior wall of the bladder without seeing or feeling the latter? The anatomical arrangement of the peritoneum is not the same in every case. I have observed a fold of it lying in front of a part of the anterior wall of an over-distended bladder on more than one occasion. Mr. Sheaf's experience with damaged gut is unfortunately not unique. I have had to operate on a patient in whom the tube had been inserted by blind puncture through the lumen of a piece of small gut before entering the bladder. As in Mr. Sheaf's case the intestine was still further damaged when the suprapubic sinus was dissected preliminary to opening the bladder for prostatectomy. The operation was made more difficult by the mass of peritoneal adhesions. Another case in which similar adhesions had sealed off the tube from the coelom had fortunately left the gut undamaged. I agree with Mr. Sheaf that in performing suprapubic drainage the catheter should be introduced into the bladder under vision. Apart from this, Mr. E. W. Riches's technique is to be commended.—I am, etc.,

London, W 1

CLIFFORD MORSON.

SIR.—I should like to reply to Mr. E. W. Sheaf's letter (March 2, p. 331), as that part of the article to which he refers was my responsibility. Although the method of suprapubic catheterization described was originally devised for the treatment of bladder paralysis (*Lancet*, 1943, 2, 128; *Brit. J. Surg.*, 1943, 31, 135), I have used it extensively for cases of retention in prostatic obstruction, and it is my routine treatment for chronic retention due to this cause. The very competent house-surgeon to whom he refers was also very enterprising in adopting the same method, although the propriety of any house-surgeon performing solely from the book an operation in which he has not had practical instruction may be questioned. The level of the puncture must obviously depend on the degree of bladder distension, and the instructions cited by Mr. Sheaf were given in an attempt to avoid the low suprapubic fistula which has been and still is, unfortunately, too common. If the bladder is adequately distended and an oblique track is made

the danger of puncturing the peritoneum is minimal; I have seen it only twice in some hundreds of cases, and each time it was recognized and corrected without harm at the time of the subsequent prostatectomy. Anatomists have stated that a bladder containing three-quarters of a pint (425 ml.) of fluid comes into contact with the abdominal wall for a distance of about 3 inches (7.5 cm.) above the symphysis pubis (Appleton, A. B., Hamilton, W. J., and Tchaperoff, I. C. C., 1938, *Surface and Radiological Anatomy*, Cambridge, p. 185), and this can readily be verified by surgical observation. Mr. Sheaf's suggestion that the puncture must usually traverse free peritoneum is at complete variance with the facts. Nor must he expect to find the bladder adherent to the anterior abdominal wall below the fistula; the avoidance of an open operation at the first stage leaves the field free of any adhesions or scar tissue at the second, and makes the exposure equal to that obtained at a one-stage prostatectomy. When preliminary drainage has been prolonged—in his case it was ten weeks—it is to be expected that a pouch of peritoneum will come down on either side of the track of the catheter, and it is therefore wiser to expose the anterior surface of the bladder at the second operation and open it below the fistula, stripping up the peritoneum and keeping strictly to the midline, just as in a one-stage operation. The accident of opening the intestine can thus be avoided.

While one must sympathize that his Christmas Day was marred by having to operate for intestinal obstruction, one must congratulate him on the successful outcome of his treatment and express the hope that this incident will not prevent his giving the method a fair trial in suitable cases; I can assure him that its advantages greatly outweigh any defects it may have.—I am, etc.,

London, W 1.

E. W. RICHES.

Psychology of the One-eyed Man and his Position in Industry

SIR.—The article on this subject by Lady Duke-Elder and Dr. E. Wittkower (Feb. 2, p. 155) has given us a timely reminder of this important problem. The eye injuries of this war and the ever-recurring eye injuries in industry are adding thousands to the present mass of one-eyed people. What is the position of the one-eyed men and women in the labour market? What jobs should they take up?

In the course of my investigations in 1938 on the employment of the one-eyed worker in industry I asked the Industrial Welfare Society to send out a questionnaire to its 750 member firms. This questionnaire asked for information about the employment of one-eyed men and women, their efficiency at work, and their accident record. Replies were received from 398 firms which employed about 1,000,000 workers. In these replies I learned that one-eyed men and women are employed in mines, iron and steel works, in the manufacture of chemical and electrical goods, and also in the fine close work necessary in the manufacture of artificial silk yarn, woollen goods, etc.

One-eyed people can be divided into two groups: (1) those who have lost an eye since childhood; and (2) those who have lost the vision of one eye in adult life as a result of disease or injury. The first group are in no way handicapped and have full confidence in carrying out their work. One finds the men in this group employed in the building trades working on ladders, on scaffolding, roofs, etc.; in the engineering trades working on every type of machine; in the tool-making industry, where great precision is required; and doing clerical work in offices. They are just as quick and efficient as their fellow men who work with both eyes. In the labour market these men and women have suffered few disadvantages until now. In recent years many large industrial establishments have instituted pre-employment visual examinations. It is obvious, therefore, that this group of one-eyed people will in future find greater difficulty in the selection of trades and professions.

The second group of one-eyed workers comprises those who have lost an eye in adult life. For the purpose of this investigation in 1938 I examined 100 men and women who had lost an eye within the previous eight years. They were patients at the Royal Eye Hospital, London, where the investigation was carried out. An inquiry was then made into the following points: (1) Trade and occupation when the accident to the eye occurred. (2) Time taken for readjustment to monocular

vision. (3) Period of enforced absence from work. (4) The subsequent employment of the injured worker. After the excision of an eye the patient takes a little time to adjust himself to the new visual conditions. The usual errors in the estimation of distances are made by all during the first few weeks following the loss of an eye. The period of the new visual adjustment takes from a few weeks to some months. Young workmen adjust themselves to the new visual conditions much more quickly than older people, who take longer to regain their confidence and remain nervous and anxious, especially when negotiating traffic in busy roads. The loss of the master (dominant) eye produces greater disability and delays adjustment to monocular vision. In assessing the loss of working capacity in a person who has lost the vision of one eye it is important to ascertain whether the injured eye was the master.

The Period of Enforced Absence from Work.—Convalescence after the removal of an eye together with the time necessary for the patient to regain confidence to return to work should rarely exceed two to three months, and yet I found during my investigation that the greater number of men, after the loss of an eye, stayed away from work for periods varying from six to nine or even ten months. A number of factors are responsible for this delay in the return to work. (1) Fear and lack of confidence to work under the new visual conditions. This may be a very important factor and cause the man to stay away for several months. Patients suffer from a genuine fear of injury to the other eye if and when they return to work. Their limitations in the field of vision and the mistakes they make in judging distances, heights, and speed of vehicles, etc., cause them to be conscious of the dangers which will confront them when they resume work. These men require careful rehabilitation. On many occasions I have advised them to carry out simple tasks at home, such as knocking nails into a board, using a screwdriver, etc. These simple exercises combined with the playing of a ball game have greatly accelerated the process of visual readaptation, thus enabling the injured men to return to work sooner. It would indeed be helpful if rehabilitation centres were established at eye hospitals. There the one-eyed men and women could receive training for specified work, and psychological treatment could be given where necessary. (2) Compensation and litigation difficulties represent the next factor delaying the patient's return. I hope that the new Industrial Injuries Bill will safeguard the interests of the injured worker and enable him to return to work as soon as he is fit. The settlement of the claim should be left to a later date after the resumption of work. This procedure would save him many months of unnecessary hardship resulting from the loss of wages. (3) The last and very important factor causing delay in the return to work is due to the unwillingness of firms to employ one-eyed personnel. It should be made well known that the experience of many welfare and safety departments attached to several large factories in this country has shown that one-eyed workers, after the initial period of accustoming themselves to monocular vision, are, for practical purposes, as fully efficient as two-eyed people. Detailed accident statistics kept by the safety departments indicate that there is no evidence to show that one-eyed persons are more prone to accidents than the normal-sighted.

I am often asked by parents of one-eyed children and by labour managers of large industrial establishments what occupations I consider suitable for one-eyed people. Of course this depends on the vision of the one good eye. If this is 6/6 or 6/9 the one-eyed person can follow comfortably all occupations involving close work (clerical work, watch-making, jewel work, and even the fine close work required in the manufacture of artificial silk yarn or hose, and the inspection and manufacture of electric-light bulbs and radio valves). In the metal and engineering trades the one-eyed man with 6/6 or 6/9 vision is fit for most jobs, but of course I would advise against employment in operations which present a greater danger of injury to the good eye. If the vision of the sound eye is less than 6/12 I would suggest that gardening, farming, or domestic service are the most suitable occupations.

The eye injuries of this war will add a large number of men to the mass of one-eyed workers. Many of them will be anxious to return to their pre-war employment. The men should be advised against returning to work which involves chipping, hammering, or drilling metal. They should not be employed

in underground work in the mining industry. Rehabilitation centres should bear this in mind when preparing them for future work. The examining factory surgeons and industrial medical officers should always remember that although one-eyed men and women are fit for most jobs the safety of the good eye should be the first consideration.—I am, etc.,

London, W.1.

Cephalin Flocculation Test in Malaria

SIR,—We read with great interest Dr. J. G. Makari's paper (Feb. 23, p. 272) on the cephalin-cholesterol test in malaria. We first became interested in the use of this test in malaria in August, 1945, and since then we have applied it to 18 cases of malaria, the results of which are tabulated below:

Type of Malaria	No. of Cases with Positive Blood or Marrow Smear	No. of Cases with Negative Blood Smears	C.C.F. 48-hour Result	
			Positive	Negative
<i>P. vivax</i> infections . . .	14	—	11	3
Clinical malaria (<i>P. vivax</i>)	—	3	2	1
<i>P. vivax</i> and <i>P. falciparum</i> infections	1	0	1	0

It will be seen from this table that our results are in agreement with those obtained by Dr. Makari. Of the three clinical cases with negative smears, two were typical benign tertian clinical cases with histories of repeated attacks of malaria, and the third case was a patient with chronic malaria who had received treatment before admission. In this case the C.C.F. test was negative on admission. The only abnormal findings were a raised sedimentation rate and splenomegaly, both of which disappeared with further treatment.

Hippuric acid liver function tests were carried out on 8 of our cases; the results varied from 83 to 122%, normal average—all within normal values. In cases we were able to follow up we found that the C.C.F. reaction became negative with antimalarial treatment; the shortest interval after commencement of treatment and the reaction becoming negative was 10 days and the longest 60 days, this last being in a case of chronic malaria with a large spleen, no pyrexia, and parasites only present in sternal marrow. Generally we found that the decrease in flocculation was closely correlated to a fall in the sedimentation rate. Our tests were carried out with "difco" cephalin cholesterol and Hanger's method was used.

We are in agreement with Dr. Makari that the cephalin-cholesterol test is an index of malarial activity in the host's tissues, and we commend his suggestion that this test should be carried out in prospective blood donors. As well as excluding cases of malaria and infective hepatitis, it would also exclude cases of infective mononucleosis. Rosenberg (1941) describes three cases of infective mononucleosis in which the cephalin-cholesterol test was positive, and we have observed it on two cases, both giving a strong positive result. Incidentally the first mention of the use of the cephalin-cholesterol test in malaria that we can find in the literature is four cases described by Pohle and Stewart in 1941. In three of these cases the patients were suffering from syphilis of the nervous system and had been treated with malaria therapy, and the fourth was a case of acute tertian malaria. We hope to publish our own results in full at a later date.—We are, etc.,

Sulphadiazine Anuria in a Gurkha

SIR,—Lieut.-Col. C. W. Healey (Feb. 9, p. 202) described five cases of sulphapyridine anuria in Gurkhas, and he concluded from his experience that they "are particularly liable to fail to excrete the products of modern chemotherapy." In Italy last year my field surgical unit was sent to look after the casualties of a Gurkha regiment engaged in the Apennine Mountains, just

before the final and overwhelming attack on the valley of the Po. Although we only treated Gurkha patients for this one month, our only case of sulphonamide anuria during that year (1945) in Italy occurred in a Gurkha patient, and the majority of our abdominal and head cases received sulphadiazine as routine post-operative treatment.

Rfn A B C, aged 20 years, was wounded on the Gesso mountain on Jan 10, 1945. He suffered from multiple shell wounds of the head and a fractured scapula. The scalp was severely lacerated and the skull was fissured but not depressed. The scalp wounds were excised, penicillin was inserted, and all the wounds were sutured. A course of sulphadiazine was given by mouth for the first four days after operation (total 25 g).

On Jan 14 no urine was passed. Fluids and alkalis—sodium citrate 60 gr (4 g) four hourly—were given by mouth in large quantities, but no urine was passed during the next twenty-four hours. On Jan 16 intravenous glucose saline was administered by drip infusion. Still no urine was passed. In the afternoon the patient had become drowsy, his face was oedematous, and his eyelids and legs were greatly swollen.

As the roads were blocked by snowdrifts and there was no possibility of obtaining a cystoscope or a ureteric catheter, a nephrostomy became essential. At 5.30 p.m. on Jan 16, under open ether anaesthesia, the right kidney was exposed and found to be swollen beneath a tense capsule. On opening the pelvis of the kidney clear urine squirted out under pressure. The capsule was stripped off the convex border of the kidney, and a de Pezzar catheter was placed in the pelvis. During the next twenty-four hours 17 oz (482 ml) of blood-stained urine were passed via the nephrostomy tube and 5 oz (142 ml) per urethrum. The patient was still oedematous and his sputum became profuse and frothy in the afternoon of Jan 17. The infusion was stopped at once and his general condition improved rapidly. During the next twenty-four hours 20 oz (568 ml) were passed via the nephrostomy and 45 oz (1.3 l) were voided normally. At 7 p.m. on Jan 18 the urine was noticed to be clear and free from obvious blood. The oedema had subsided considerably. Next day the patient was cheerful and alert, and the oedema had disappeared. Henceforth he passed clear urine in normal volume each day.

The patient was allowed up on Jan 26 and the nephrostomy tube was removed next day. He was evacuated to the rear on Jan 29 and his M.O., Capt. Naqi, M.C., I.A.M.C., reported that he ultimately returned to duty some weeks later.

I believe that sulphonamide nephrosis, or ureter obstruction due to crystal precipitation, can be prevented in nearly all British patients if there is an adequate fluid intake—5 to 6 pints (2.8 to 3.4 l) daily. However, if the fluid intake has been allowed to fall whilst the drug is being administered, oliguria, pain in the loin or epigastrium, and haematuria may occur. In this early stage the patient can be treated successfully by intravenous glucose-saline infusion. Alkalis may possibly help, but I am not convinced of their efficacy. If anuria is allowed to ensue, washing the pelvis out with saline through the ureteric catheter usually relieves the patient. If this process fails or is impracticable, a nephrostomy, performed in good time, can usually be relied upon to save the patient.—I am, etc.

MICHAEL C. OLDFIELD

Ocular Signs in P.O.W.s from the Far East

SIR.—The condition referred to in both Dr. H. G. Garland's and Capt. W. M. Rich's letters (Jan 26, p. 143, and March 2, p. 330) is one well known to observers in West Africa and other tropical countries. For the first time, apparently, it has now been observed in Europeans, and under conditions permitting accurate observation. During my time as Army ophthalmologist in Freetown, from 1941 to 1943, I have seen a large number of these cases among native troops. They were at that time regarded as a "kind of avitaminic retinopathy." I ran some series of vitamin administration: red palm oil (retinol), vitamin A and D, pure riboflavin, marmite, and nicotinic acid. Uniformly negative results forced me to the conclusion that the condition was not an avitaminosis, at least not one in the accepted sense of the term. Investigations into the customary diet of these men, however, made me suspect a protein deficiency, or rather a "poisoning" by certain kinds of low-grade protein.

Last summer, in Rangoon, when thousands of relieved P.O.W.s and internees passed through our military hospitals on the first stage of their way home from Thailand and Indo-China, we found about 1% of the men suffering from an identical complaint. The history given by the men and the disappointing

results of vitamin administration brought me to the same conclusion I had reached two years before: that the so-called "avitaminic retinopathy" was not caused by lack of vitamins at all but by some toxicosis due to lack of good proteins or to certain low-grade proteins. In addition there seemed some constitutional and psychological factors involved.

It was interesting to listen to the nearly stereotyped case histories related by these men, how they dated the beginning of their complaints to a period of uniformly bad diet in the spring of 1943, and how in the time following they observed temporary improvement of their vision whenever an egg or a scrap of meat could be obtained. On hearing such a story every contemporary medical observer with his vitamin-conditioned mind will jump to the seemingly obvious conclusion—and then be disappointed by unsuccessful treatment. There is, of course, the true retinopathy of beriberi which invariably leads to optic atrophy. Optic atrophy of the papillo-macular bundle was indeed observed frequently, but its occurrence bore no relation to the incidence of the scotomata, which rather seemed to be an independent symptom of this peculiar toxic amblyopia.

While I do not claim any originality for these views, I hope that these remarks will help to throw more light upon this rather puzzling condition—I am, etc.

Specialist.

Quinine for Induction of Labour

SIR.—I read with interest Dr. Eneas Mackenzie's letter (March 2, p. 333) on the use of quinine for medical induction, but am rather at a loss to discover what exactly he is able to prove by the figures which he gives. It would appear that he disagrees with Mr. Neon Reynolds's statement that the use of quinine is a "thoroughly bad practice which is productive of many stillbirths each year." He then goes on to say that in 105 cases out of 647 he used quinine as a method of induction without a single stillbirth.

First, I would like to point out that a series of this size proves very little, it is not, in fact, statistically "significant." On the other hand, one must say in fairness that all the available evidence is not on the side of Mr. Reynolds and against Dr. Mackenzie. Dilling and Gemmel (*J. Obstet. Gynaec. Brit. Emp.*, 1929, 36, 352, 1930, 37, 529) record their observations on the dangers of quinine in these words: "Although there is experimental evidence to prove that quinine may cause intra-uterine death, statistics show that this risk is not greater than that of stillbirths from undiscovered causes in otherwise normal labours." Dodds (*J. Obstet. Gynaec. Brit. Emp.*, 1931, 38, 827), in a series of 338 cases, came to a similar conclusion. On the positive side, however, Munro Kerr denies that the use of quinine has any influence on either the duration of labour or uterine inertia; and on page 69 of his *Operative Obstetrics* mentions that Theobald (*Journal*, 1943, 2, 851) recommends it very strongly, while Buddee (*ibid.*, 1934, 1, 1159) questions its efficacy.

I would like to know, however, exactly what the following statements in Dr. Mackenzie's letter are really meant to convey.

1. "I have found it a most helpful procedure." To whom is it helpful—to the mother, the baby, or the doctor? How may this helpfulness be assessed?

2. "There is a proper stage in pregnancy when quinine can be used with safety and success." This is a simple and dogmatic statement made without any statistical backing. How does Dr. Mackenzie arrive at an estimate of propriety, safety, and success?

3. "To use it at the wrong time and in the wrong type of case is to court disaster." This is true of practically any method in use in operative obstetrics—in forceps delivery, version, and Caesarean section, to mention a few only. What are the right times and the right type of case?

4. "I am, of course, not an F.R.C.O.G., and not even a D.R.C.O.G., and I have not been within a maternity hospital for 40 years; I am only a rural practitioner with no begowned, bemaused, and begloved assistants to help me, only a district nurse and 'an auld wife to haud a leg.'" Possibly had I Mr. Reynolds's qualifications and bevy of assistants I might have his results. As Dr. Mackenzie has been permitted to lapse into the idiom of "braid Scots" perhaps I may be allowed to

do the same, and to inquire whether it is by any chance possible that he has a "scunner" (dislike) for such new-fangled notions as higher obstetric qualifications, maternity hospitals, gowns, gloves, masks, and the like.—I am, etc.,

London, W.1.

D. G. WILSON CLYNE.

Penicillin in Gonorrhoea

SIR,—In his article "Penicillin in Gonorrhoea" (March 2, p. 314) Dr. Alastair Allan stresses the need for a follow-up lasting twelve months in cases of gonorrhoea treated with penicillin. It would be interesting to know what facts or theories have led Dr. Allan to advocate this long period of surveillance.

My own observations in cases of gonorrhoea¹ treated with penicillin in doses of 100,000 units by the divided dose method have led me to believe that the six-months follow-up used in the Allied Armies is adequate. Indeed I have not yet seen any cases where syphilis became evident later than three months after penicillin therapy for gonorrhoea and without another exposure to possible infection. The incubation period of syphilis is lengthened by penicillin in the dosage used for gonorrhoea, but when signs of disease appear they are in no way altered, and *Sp. pallida* is readily demonstrable in primary lesions. In my experience, even after the treatment of syphilis itself with penicillin in doses of 2,400,000 units, cutaneous and mucous relapse phenomena appear in the majority of cases within six months after treatment.²

I think that Dr. Allan is overestimating the antispirechaetal powers of small doses of penicillin, and that any improvement in his default rate caused by speeding up actual treatment will be offset by the length of the surveillance period. It would be interesting to have the reasoned opinions of your readers on the length of follow-up necessary after the treatment of gonorrhoea with penicillin in the doses now used.—I am, etc.,

London, S W 1.

Penicillin and Pursers

SIR,—It is interesting and comforting to read in Mr. James Hall's most instructive article (Feb. 16, p. 244) that penicillin is used (and with satisfactory results) under the direction of the pursers of many American ships. Surely the time has now come when the general body of practitioners in this country may be trusted with the precious stuff. I write not only as one of the "ninety-and-nine" unprivileged general practitioners whose work over the past few years has been from time to time embarrassed by this invidious veto, but also as one who, thanks to the timely action of a specialist colleague, owes his very life to penicillin therapy.—I am, etc.,

O. P. CLARK.

Anaesthesia

SIR,—Dr. W. A. Bellamy (Feb. 16, p. 252) bows his devoted head awaiting the storm to burst: and I am sure it will burst indeed before very long. I should like to add my raindrop to the storm.

He deduces from the fact that the percentage of anaesthetic deaths has not decreased during the last fifteen years the curious conclusion that the older methods are equal in efficiency to more modern and elaborate techniques. It would appear to me (and I am open to correction by any statistically minded colleague) that this deduction is unsound. Surely it is since the introduction of these "tubes, taps, and turncocks" that surgery has become safer for a large class of patients who were poor risks under the open ether and chloroform techniques; and so a multitude of patients are submitted to surgery now who would not have been operated on at all previously. Thus it seems that if this mass of poorer-risk material is included in the statistics of anaesthetic deaths, the fact that the death figure is so constant is a credit to the newer methods. Furthermore, the percentage of deaths is not the only index of the success or failure of any anaesthetic method. The time the operation takes, the look of satisfaction or otherwise on the surgeon's face, the recovery time of the patient, and the inci-

dence of post-operative complications, pulmonary and otherwise, all must be considered. The anaesthetist usually sees only the first two of these. As a house-surgeon I have seen the others, and over a period of many months, with various classes of patient, I have been able to foretell with reasonable accuracy who was going to be "chesty" after operation, who was going to have to endure the agonies of prolonged sickness after operation, simply by looking at the anaesthetist's name and knowing what method he used. If an anaesthetist wants to know if he is a good anaesthetist or not, he should consult the people who see his cases in the post-operative period—the housemen and the ward sisters. They know very well indeed who is good and who is bad without ever, of necessity, seeing the person concerned, or seeing whether he is a "tube-and-turncock" or a "rag-and-bottle" merchant.

But from my experience it is the open-ether patient who suffers most with chests, "ether eyes," and sickness. These things naturally do not alter the percentage deaths very much, but they do mean much to the patient both in the matter of comfort and in the willingness to have an anaesthetic again. With open ether one can give a good anaesthetic, of that there is no doubt; but one can also shoot a rabbit with a blunderbuss, and doubtless shoot it very well. The advent of "tubes, taps, and turncocks" does not of course by itself make the anaesthetic better, but it does place in the hands of the operator better and surer ways of controlling his anaesthetic agent. It is the anaesthetist who controls his agent who has the best results, interpreted in terms of help to the surgeon and post-operative comfort of the patient. Of course, to use the newer and more complicated machines one must study them and learn their uses and limitations. Shockingly bad anaesthetics can very easily be given using one of the most efficient machines if the operator does not know how to employ the control methods at his disposal.

I am glad to hear Dr. Bellamy say that housemen cannot give open chloroform. I have never given chloroform nor seen it used. I hope I shall never have to give it so long as safer agents continue to be available. It is, I feel, quite true to say that really good anaesthesia by inhalation methods is "a cult known only to a favoured few," and this few is only favoured in so far as they have the intelligence and common sense to study their equipment, use it carefully, choose the agent most suiting the patient and the operation, and, above all, at every stage, to control the anaesthesia.

Modern machines are designed so that the anaesthetist has perfect control over what the patient is breathing and when he breathes it. There are no superfluous knobs, taps, or tubes. The careful and skilled anaesthetist has welcomed these machines because they give him ever-increasing control of the anaesthesia; and he will continue to use them to the benefit and comfort of surgeon, patient, and staff, irrespective of whether percentage deaths fall over a period of fifteen years or not.—I am, etc.,

Aberdeen.

MALCOLM R. MILNE.

SIR,—As an anaesthetist devoted to the art and banded together with Dr. A. H. Galley in the Anaesthetics Section of the R.S.M., I should like to congratulate him on his admirable reply (March 2, p. 332) to Dr. Bellamy's nostalgic wail over the otherwise unlamented passing of an era in anaesthesia characterized by a high incidence of post-operative morbidity. My feelings, however, were more poignant, since for twenty years I have striven to associate Aylesbury with progress in anaesthesia and have pleaded in the columns of the *Journal* for an eclectic attitude and flexibility of technique, whereby the drug or method calculated to produce the best result in each individual case may be employed.

With regard to "over-specialism," Dr. Bellamy's devoted head has remained so bowed that he has not noticed that the trend of the specialist anaesthetist is not to limit but to enlarge the scope of his activities, so as to include not only all branches of anaesthesia and analgesia, but also oxygen therapy, resuscitation, pre- and post-operative treatment, etc., the high value of his services in which has been abundantly proved in the late war. It would appear a far greater danger that he himself should become a super-specialist, such as an "avertinist" or "tribromethylalcoholist." Concerning simplicity, one of the

most famous last words (for the patient!) is, "Just give her a shift, old man."

I should like to invite Dr. Bellamy to journey into Ashbury and meet Mumbo and Jumbo (two fairly modern closed circuit machines so christened in his honour) and see for himself that they, in conjunction with their jungle pal Circe, are not so lethal or so complex as his perfervid imagination would lead him to believe—I am, etc.,

For the Hospital Ashbury H. W. LOFTUS DALE

Liver and Spleen Puncture

SIR—It has occurred to me that the production of apnoea by overbreathing would make the operations of spleen and liver puncture easier and safer. The danger of these procedures is haemorrhage from tearing on respiratory movement while the instrument used is *in situ*.

According to Yandell Henderson (*Adventures in Respiration*) a normal man at sea level can stop breathing for 40–60 seconds. After forced breathing of air he can hold his breath for 2–3 minutes. Breathing then recommences owing to oxygen lack and is periodic at first. If, after several minutes' forced breathing, he fills his lungs with oxygen he can hold his breath for 5–6–10 minutes. Breathing recommences without periodicity when sufficient carbon dioxide has accumulated. There is no oxygen lack.

Each patient could have one or more rehearsals to find out how long the apnoea in his case would be likely to last. Hyperventilation tetany is rarely produced by a few minutes' overbreathing, if it should occur and not pass off quickly when the overbreathing ceases inhalations of oxygen and carbon dioxide 5 to 7%, or rebreathing from a paper bag will stop it.—I am, etc.,

St. Benedict's Hospital
London S.W. 17

MARY WALKER

The E.S.R. Technique

SIR—I am sorry to find that Dr. H. S. Gaskell (Feb. 16, p. 255) is not to be persuaded that the tube-length within wide limits makes no difference to the result when the rate is normal. It is something to find that he does admit that we should both sink at the same rate (barring the effect of salt water) in the Pacific as in the local swimming-bath, and I can assure him that the same principle applies to the rouleaux of red cells in the sedimentation rate. Stokes's Law makes no allowance for the distance the sinking body has below it, as the body soon attains a constant velocity.

When on the Committee of the E.S.R. of the Empire Rheumatism Research Council, my colleague and I worked out the whole subject of tube lengths and bores at very great length, and I have voluminous records made on the automatic recorder of bloods put up simultaneously in tubes of widely varying bores and lengths. Even in tubes of 25-mm length the normals come out the same at the end of the hour, and it is only when more rapid rates are measured that the short tubes give lower results as a consequence of the earlier onset of packing. I can only imagine that Dr. Gaskell is thinking of these. I will gladly send him some of my charts if he is interested.

I am sorry to hear that Messrs. Hutchinson and Hunter have been so misguided as to call plasma "serum," especially in a test in which some authorities consider the fibrinogen to play a most important part—I am, etc.,

London W. 1

J. W. SHACKLE

Traveller's Oedema

SIR—Dr. Zaccopoulos's remarks (March 2, p. 322) about traveller's oedema reminded me of a similar condition which was prevalent among older people in a deep tube shelter to which I was medical officer during the "blitz." It was particularly noticeable before bunks were put up, the more select who did not wish to lie on the platform brought deck chairs, and I think the bar behind the knees was partly responsible.

In Sept., 1922, it was my fate to travel from Corfu to Trieste in a rather superior boat containing Greeks and a sprinkling of Armenians from the Smyrna "episode." These people had had their nerves frayed by what they had been through, and

they grumbled bitterly to the captain. His deck was so small that they had no exercise and were suffering terribly from swollen legs and constipation. I heard the exasperated Italian captain say, "Look at that Englishwoman over there. I don't know what devilry she is up to now, but she is never still, and I bet you she has no constipation or swollen legs." And he was correct—I am, etc.,

London N. 1

LINA M. POTTER

SIR—In his paper on traveller's oedema (March 2, p. 322) Dr. Zaccopoulos does not mention two important aetiological factors: (1) The severity of the condition is much aggravated by a hot, particularly a hot and humid, climate. It commonly occurs amongst the crew of ships in the Tropics, yet I have never seen it in Northern waters. The circumstances of Dr. Zaccopoulos's cases—a rail journey from Smyrna to Aleppo—suggest that the heat factor with its concomitant sluggish circulatory condition was present. (2) Tall asthenic people who have a poor circulation anyway, who faint easily, and whose extremities are always icy in cold weather, are usually first affected and develop the grossest swelling. It would be interesting to know the nutritional state of these soldiers. If the oedema of starvation were just around the corner, it might account for the very high incidence amongst them—I am, etc.,

Barking

G. S. WIGLEY,
Sergeon-Lieut.-Colonel, R.N.A.F.

Physical Therapy in Mental Disorder

SIR—Without wishing to enter any controversy regarding any comments of Dr. Leroy concerning Dr. Frank, may I associate myself with Dr. Leroy's letter (Feb. 16, p. 251) regarding convulsion therapy? What he says concerning its use as a punitive measure is unfortunately occasionally true. So is the indiscriminate use of a method which is valuable in the right cases. The following instance exemplifies the effects of its too facile use on the laity.

Recently while in the Middle East I was called into a hotel to see a middle-aged patient, who appeared to be developing a paranoid psychosis, though he had very good insight. He also had diminished ankle jerks. Nevertheless a doctor who had seen him the day before had, without more ado, prescribed ECT to be given in the hotel. Largely, I suspect, to rubberstamp this surprisingly popular prescription, three psychiatrists, including myself, were then called in. (In the country in question it is the custom for consultants, like troubles to come not single spies but in battalions.) We all agreed that a lumbar puncture was indicated, that a hotel, however luxurious, was not a suitable place for an incipient psychosis, and that, if the condition was not organic, in view of the good insight psychotherapeutic measures had a place in treatment. Also that certainly until investigations were completed ECT. was not indicated.

We explained this to the patient's mother. She vigorously resisted any question of investigation or hospitalization, and when we said that, at least pending investigation, we thought ECT contraindicated, she exclaimed in horrified tones, "What, you do not wish him to have electric shock treatment?" and burst into hysterical sobs. The mother was undoubtedly a foolish woman, but even making allowances for that, the fact that an over-solicitous mother should be reduced to tears because caution was advocated in giving her son repeated major convulsions, is surely a striking commentary on a tendency to lade out fits as though they were nothing more drastic than an aspirin tablet—I am, etc.,

W. LINDSAY NEUSTATTER

Homosexuality

SIR—I cannot claim the specialized psychiatric experience and authority which might be regarded as a *sine qua non* for participation in this discussion, but I have recently had the opportunity of debating the subject with a friend who in a past official capacity had considerable responsibility in the conduct of prosecutions for offences which included those under review, and I think the impressions I have derived are worthy of communication to your columns.

My friend was candid in admitting an innate hostility towards defendants whose acts tended towards any injury of children, and he had no hesitation in segregating homosexual offences between adults as wholly distinct from those where children were involved. And, perhaps in consequence of such acknowledged bias, he criticized the exaggerated emphasis laid by the majority of your correspondents upon the position of the defendant to the exclusion of the dangerous effects which might be caused to the victim. Unless defendants in such instances can be classed as insane in the eyes of the law, it was only to be expected that courts should regard their acts as calculated and deliberate *vis-à-vis* their victims, and in this respect any "pathetic" element—to use a phrase of one correspondent—should apply to the victim rather than to the malefactor. On that basis, sentences which superficially appear unreasonably vindictive are justified to ensure protection of potential victims.

In my friend's experience those offenders, the subjects of a perversion which demands a child as participant, were in nearly all cases irreclaimable.—I am, etc.,

London, W.1

ADOLPHE ABRAHAMS.

SIR,—I have followed this correspondence with interest and bewilderment. Surely the first letter concerned an individual charged and convicted not with homosexuality as such but with repeated assaults on several children over a period of years—and assaults on children, whether homosexual, heterosexual, or sadistic, are regarded with disfavour by community and law alike. What two like-minded adults may do in privacy is very possibly their own concern, but this does not seem to be the point under debate, and perhaps it is partly because homosexual practices not infrequently result in assaults, and receive publicity in this way, that the opinion of the majority disapproves of such practices. If the community takes power to protect its property by means of the preventive detention of habitual criminals it may surely protect its children by similar means.—I am, etc.,

Birmingham

KATHLEEN A. H. SYKES.

Stethoscope versus X Rays

SIR,—Dr. E. Weatherhead (Feb. 23, p. 293) states: "Moreover, clinical evidence will often give more information as to activity or non-activity of pulmonary disease than is to be got from x-ray examination alone." As the terms "activity" or "non-activity" are never applied to any other pulmonary disease but pulmonary tuberculosis, I assume that Dr. Weatherhead means pulmonary tuberculosis. I have no intention to argue about the correctness of this statement, and I am writing only to draw attention to a gross fallacy which is hidden in it.

If by *clinical evidence* Dr. Weatherhead means auscultatory findings obtained by the use of the stethoscope, then the statement is absurd. On the other hand, if in *clinical evidence* he includes—and I must assume that he does—the interpretation of the temperature chart, pulse chart, weight chart, the results of haematological and bacteriological tests, and the application of exercise tolerance tests, then the statement has no bearing whatsoever on the present correspondence or on the opinions expressed by some members of the Royal Society of Medicine in their debate on "Stethoscope versus X Rays," to which some participants of this correspondence, including Dr. Weatherhead, so strongly objected. Indeed, in the light of Dr. Weatherhead's statement, the poor stethoscope strongly resembles a fifth-rate provincial "soccer" club entering the field on a special occasion with ten guest players—of international reputation.

Don't let us confuse the issue. The debate in the Royal Society of Medicine was not on "X Rays versus the Rest." It was clearly on "Stethoscope versus X Rays," which can be summarized in two questions with two simple answers: *Question 1.*—What evidence of pulmonary disease can be detected by auscultation which could not be detected by x rays? *Answer.*—Rhonchi and pleural friction rub. *Question 2.*—What evidence of pulmonary disease can be detected by x rays which could not be detected by auscultation? *Answer.*—Innumerable.

I whole-heartedly agree with Dr. Weatherhead that "the importance of this controversy lies partly in the fact that some of the statements made at the Royal Society of Medicine

debate came from members of the teaching staffs of one or other of our own great London hospitals and might therefore be accepted as authoritative by junior members of the profession." The authority of Dr. James Maxwell, Dr. Peter Kerley, and Dr. Geoffrey Marshall needs no endorsement by the profession. Let us hope that the overwhelming majority of the junior members of the profession will take their teaching to heart and by insisting on x-ray examination, in spite of negative auscultatory findings, will succeed in saving many lives, which would have been inevitably lost without adequate radiology.—I am, etc.,

F. KELLERMANN,
Assistant Medical Officer, Essex County Council

Haematuria after Injection of Haemorrhoids

SIR,—I was interested in the case of haematuria after injection of haemorrhoids quoted by Dr. Kenneth Hazell (Dec. 15, 1945, p. 864), for I have had one case recently. In this case 3 ml. of 5% phenol in almond oil were injected submucosally above the haemorrhoid, and when the patient reported one week later he stated that during the evening after the injection, which was given in the afternoon, he had painless haematuria. This had ceased by the following day.—I am, etc.,

Melbourne.

S. L. STRANGE.

A Fundamental Principle

SIR,—At this hour it is encouraging to be able to assume that opinion is hardening against the introduction of a compulsory State service. I assume, that is, for one cannot suppose that you now depart in the least from your traditional policy of publishing a representative cross-section of all views, and there has recently been a sharp decrease in the number of letters in the *Journal* that truly support the planners' case.

Some of the exceptions continue to make strange reading. Whence does Dr. J. H. Wilson (Feb. 23, p. 295) derive the quaint conceit that doctors "never, never can be slaves" in virtue of their liberal and cultural background? In the first place, medicine is often pilloried as a technical body of men greatly inferior to those of other professions in regard to liberal culture. In the second place, a background of social and intellectual refinement does not confer the slightest immunity to enslavement; history may even be interpreted as suggesting that it may be an enervating influence conducive to slavery, as in the case of the ancient Greeks, for example.

The trite, poetic, and philosophic stress on the inalienable freedom of the mind hardly seems in issue when one is faced with the *de facto* legal status of slavery. If the antislavery workers in America a few generations ago had been impressed by these vague arguments they would have accomplished little. The physician-slave of ancient Rome seems to have enjoyed amazing freedom as contrasted with the position which his twentieth-century counterpart is likely to occupy: he had a wide discretion in technical matters, could often move freely about the land, could always take private patients, and was even encouraged to gain a fortune and perhaps to purchase his freedom with it. The Socialist student of history will be astute to prevent such lax abuses from recurring in future.

Again, Dr. Lennox Johnston (*Supplement*, Feb. 16, p. 35) deplors the reaping of the richest rewards in present-day practice by "the popularity-seeker and the humbug." One is amazed by the implied assumption that the seeker after popularity always obtains it, and that the humbug in England to-day can "fool all the people all the time." When will so perfect a State service be devised that popularity-seekers and humbugs can make no headway? The popular doctor (as opposed to the mere aspirant towards popularity) is in a position to do great good, and Mr. Somerville Hastings shows a wise and practical grasp of realities when he suggests popularity with patients as a standard for fixing remuneration in the new service, for general practitioners at least. His suggestion sounded strange in the mouth of a Socialist reformer, perhaps because it was such a good one.

And letters still emerge in print stressing *ad nauseam* how unthinkable and contrary to public policy would be a strike of medical practitioners. From the doctor's point of view the question of striking can never arise while independence is preserved; those who refuse to sign on the dotted line will not

have had the matter in their thoughts. From the public point of view the community can never even be threatened with deprivation of medical services unless and until the latter become a monopoly. And it seems possible also that rabid Socialists who enthusiastically surrendered their professional freedom too hastily and later became disillusioned and dissatisfied with their working conditions might find themselves obliged to stage a strike as the only available means of redressing their grievances. I can conceive of a medical strike within the ranks of a State medical service and nowhere else—I am, etc.,

Stratford-on-Avon

PETEP PARRY

SIR—From Dr J H Wilson's letter (Feb 23, p 295) it is clear that in order to obtain a supply of doctors for undesirable localities he prefers nationalization and compulsion of the profession to improvement in pay and conditions or service in such areas. Those who disagree with him are entirely selfish and unconcerned for the welfare of humanity as a whole. Would not humanity as a whole include the doctor's wife and family are they not to be considered? Or perhaps Dr Wilson might agree to further "direction" as to elabouration of the doctors concerned, it is quite conceivable from the tone of his letter.

With regard to the undesirable localities the first necessity or the welfare of the people is, of course, improvement in housing environment, sanitation, more attention to character training, etc., the presence of a few more doctors would hardly affect these matters which call for immediate attention.

It would be interesting to know what is meant by "the government is about to take the cure out of our hands" presumably by conscription and exploitation of the profession. While there can be little doubt that the planners of to-day may take every advantage of the fact that the ethics of the profession could interdict such a step as "striking," it should be apparent that if the profession or even a percentage of it were to adopt quite simple "non-compliance" procedure and still treat their patients, it would not be possible for bureaucracy to impose conditions which were not acceptable to the profession. It is surely obvious that this national medical service venture was not so much a political move as an attempt on the part of the State machinery to get complete administrative control of the medical profession. If in doing so they should be so injudicious as to antagonize the profession it is quite certain that it will not be for the benefit of the public—I am, etc.,

St Mawes Cornwall

B H SHAW

The Minister Listens

SIR—It is indeed pathetic to read the trend of so many of the letters referring to the forthcoming National Health Service—letters which are commencing to appear again after your article entitled 'The Minister Listens'. The trend of many of these can be summed up in the one word "sabotage". Sabotage is advocated before even the broad framework of the Bill has been put together, sabotage is enjoined before we know what the Bill proposes to do or how it proposes to do it. Sabotage he wishes of the electorate expressed so definitely less than eight months ago and reinforced in every by-election since, sabotage the acts of the elected representatives of the people—representatives poured into Parliament by a determined nation.

There has already been more than enough sabotage. We remember that Sir William Beveridge's report was kept in cold storage for two years by the forces of the last Government and was then followed by a White Paper which probably would have sufficed for another two years had not that Government been thrown out so decisively. We remember the protracted discussions with the B.M.A. and surely must assume that the Association's comments and objections to a National Health Service, and to the White Paper in particular, were all noted and annotated by a Minister who showed no trace of enthusiasm himself for taking concrete steps to make a reality of Assumption B.

The present Minister has before him, therefore, all the B.M.A.'s objections to even so milk and water a scheme as was set out in the White Paper, and the Association's suggestions to set up a few experimental health centres and proposal to report back on their working in the fullness of time. The present Government is one of action, and we cannot expect it

to fall for any more of these Fabian tactics. Hence 'The Minister Listens'. No doubt he could indulge in months and months more of argument with our Association in the old tradition, but he appears, strangely enough, to prefer to get on with the job for which he was appointed, and for which a vast electorate is waiting.

Is it necessary for so many writers to advertise that doctors are unable to consider this scheme from any but their own narrow professional viewpoint, and indeed do not pretend to do so? That they cannot see the wood for the trees? That it matters nothing to them whether the wishes of the nation are implemented—or indeed the welfare of the multitude improved—so long as they and their methods, their convenience and their emoluments are left unchanged in a world which is continually changing? And that, indeed, if there is any attempt on the part of some 40 millions to change the ways of some 50,000 of God's anointed for the benefit of their fellow men and to fit them into a more modernized, humane, and democratic framework for the national good, then they will call for the unity of all doctors to sabotage, sabotage, and again sabotage their share of the scheme, before even the proposals have been put into concrete form? Does any onlooker suppose that we are improving our chances of being allowed—yes, I say allowed—as responsible and important a part as we might otherwise have in the shaping of one of the memorable milestones of our history? The Minister listens—and the world looks on—I am, etc.,

London.

P G S DAVIS

A Critical Layman

SIR—Having happened on your issue of Feb 23, I find that it calls loudly for at least three lay comments.

1 *Diagnostic Acumen of the G.P.* (p 294)—Why are the general practitioners so shrinkingly modest? The G.P. knows the patient as a person, and treats a person, the specialist merely treats a diseased organ. It is the G.P. who matters, and the specialist is simply one of his tools like the stethoscope only noisier and more expensive. It can do what he can't out it cannot understand what it does. Dr Mackay (believe it or not) remarks that the day may come when everyone will be referred to the appropriate specialist by a sorting clerk. It may indeed if the medical profession loses the power of independent thought. The view of the specialist as executive to the G.P.'s sorting clerk, instead of departmental adviser to the G.P.'s prime minister, is simply a relic of a philosophy of science already recognized (outside medicine) as superficial in 1910 and now merely regarded as a regrettable digression in the history of science. The single factor theory of science died for ever with the advent of the quantum theory and the relativistic theory (to say nothing of Freudian theory and its derivatives).

2 Above all else it is the importance of the G.P. and his personal relationship with his patient that you need to drive into Mr Bevan's mind now when he is listening (p 296). Yes, what you allow him to hear is exemplified by Dr Gair Johnston's sentence on page 42 of the *Supplement*: "Nationalization has always been a failure wherever it has been tried and always will be until humanity become robots which God forbids!" Knowing the importance of what they must make secure in a State medical service (which, in some form or other, is quite inevitable), it must be bitter for many members of the medical profession to find themselves supported by statements that can only give the impression that they have no rational case because they have not tried to think of one. I cannot help feeling that it is a mistake to allow so unfortunate a sentence even to slip into print.

3 When health centres are discussed why is the Peckham Health Centre, the only one aiming positively at health ignored? When the profession discusses health centres with the Minister it apparently means merely centres where disease, not health is investigated and disease alone is treated. Why not call these places "disease centres" and keep the name "health centres" for organizations of the Peckham type? And may there be many 'health centres'? Incidentally, a family doctor is possible in a health centre where he sees the whole family, but not in a 'disease centre' in which he sees only sick individuals. The true G.P. must be a family doctor. Beware that with the march of pseudo-science you don't lose him altogether—I am, etc.,

H W HECKSTALL-SMITH

Are the People More Healthy?

SIR,—Statistics such as those in your leading article (March 2, p. 318) are apt to leave one cold, particularly those issued by Government Departments for propaganda purposes, especially when one remembers the reception given to our attendance records on the last occasion we attempted to get a living wage for N.H.I. work. In my experience, and probably in that of all G.P.s, the general health is much below par. This is shown by the lowered resistance to trivial complaints, the time taken to recover, the tendency to relapse, and the prevalence of deficiency-type skin troubles. My visiting list is now longer than at any time during or before the war, in spite of the fact that I am not attending any patients of my absentee neighbours, who have returned to their practices. I consider that this is due to the strain of the war and the inadequate and monotonous diet on which we are still subsisting.—I am, etc.,

South Godstone.

H. E. GIBSON.

Tuberculosis in Childhood

SIR,—Dr. W. D. Gray's plea (March 2, p. 327) for more "preventoria" for children, suspect of tuberculosis but indefinite, seems to carry us back 30 years or more when medical opinion was far more favourably disposed to such provision than it is to-day. Some local authorities made quite generous arrangements, as instanced by an 80-bed sanatorium-school block added to an adult institution of about 120 beds; now only 25 remain allocated to children.

It is significant that Dr. Heaf's plea for more collective research is placed alongside Dr. Gray's letter. Lack of knowledge leads us to swing around with gusts of opinion for or against a given policy, with the result that "the infection continues to take toll of children and young adults as it passes through the population practically unchecked." A weighty indictment this from Dr. Heaf which Dr. Gray's subsequent letter illustrates with poignant clarity.—I am, etc.,

Moor Park, Middlesex

ESTHER CARLING.

The Colonial Medical Service

SIR,—If the leading article (Nov. 17, 1945, p. 693) was meant to "arouse interest among the younger members of the profession" as Mr. R. Ogier Ward says (Dec. 1, p. 781) then I think the many things that spoil the extremely interesting side of one's professional life should be brought to the notice of doctors intending to join the Colonial Medical Service.

In the advertisement periodically placed in the *Journal* by the Colonial Office for vacancies in the Colonial Medical Service, the service sounds most attractive with rosy prospects. "West Coast" (Jan 12 p. 65) has already mentioned some of the defects and grievances. I, too, do not think many offers will be received from specialists if the salary is to be £1,300 a year. It is grossly unfair to allow private practice, as there are not many stations where private practice is available, and, as "West Coast" says, this leads to endless intrigue. If £150 is given in lieu of private practice this should be over and above one's salary. Little recognition is given of postgraduate studies and improvement of one's qualifications, with the consequent deplorable state of affairs that if you sit down and "do not blot your copy-book" you will do just as well as the man who has higher qualifications and will get the same pay. This does not encourage initiative.

In the advertisement put in by the Colonial Office no mention is made of the administration which the M.O. is called upon to do. This may amount to quite a lot, particularly if the hospital is owned by the Native Administration; so much so, that it is often difficult to find time to practise medicine. Surely it should not be the responsibility of the M.O. to check inventories of linen, etc., as is the case in the more numerous smaller stations without a sister. Again, if the hospital is owned by the Native Administration the amount of correspondence to be entered into with the Administrative Department to obtain money for any extra needs, however urgent, is simply amazing. Furthermore, I do not think it ought to rest with an administrative officer, often only too ignorant of one's needs, as to how much money one can have to purchase drugs, etc.: rather like the butcher, the baker, and the candlestick-maker telling the doctor what he ought and ought not to have. It is an analogy of this that

we must prevent at home in the future under a State medical service.

Both Mr. Ogier Ward and Dr. R. B. Wellesley Cole (Dec. 22, p. 895) emphasize the importance of training more African doctors as an answer to the many difficulties that arise. But it is common knowledge that African M.O.s gravitate to the larger towns, entering private practice with the more attractive financial prospects. Even the African assistant M.O.s trained at the Government's expense leave Government service as soon as their contract expires, for the same reason.—I am, etc.,

"EXIT."

Final M.B. Examinations

SIR,—The memorandum on the teaching of tuberculosis to medical students (*Journal*, Jan. 12, p. 60) concludes by suggesting "that those diseases which have the highest incidence should receive priority in a teaching syllabus, even if it meant sacrificing time on the rare conditions which always have a fascination and often assume an exaggerated importance in medical education for a qualifying degree."

At the last Final M.B. examinations in two universities one question out of six on the medicine paper was on the subject of pink disease. This disease is described in Conybeare's *Textbook of Medicine* (6th edit.), under the heading of "erythroedema polynuritis," in twelve lines. Sir Henry Tidy is slightly more generous in his book and gives half of one of his thousand pages to the subject.

At one of these examinations I, as a so-called returning doctor, had decided to sit for my university degree. I had been invalided from the Services in 1943 with an apical lesion, and during the next two years had been in partnership in a busy general practice. Health reasons, however, forced me to give up the latter, and it was during an advised three-months rest that I decided to sit for the examination. My knowledge of the three final subjects was consequently based more on experience than on theory, and in my humble opinion was the average knowledge of an average general practitioner. My knowledge of pink disease was, of course, scanty, and my veiled attempts in my written reply to tell the examiner I thought it was a stupid question doubtless did not enhance my reputation with him. One of my surgery cases was an actinomycosis of the jaw, which had originally been referred to a general surgeon by a general practitioner and treated as an osteomyelitis. This treatment having proved unsuccessful, the case was eventually transferred to a great teaching hospital, and after some weeks there the ultimate diagnosis was reached. When I told the examiner that the diagnosis would not have occurred to me but for the suggestion of a friendly ward sister my reputation was again by no means enhanced. This was despite the fact that I knew the treatment. This examiner's partner in crime was even more ludicrous. I was shown a pair of artery forceps, which I described as a pair of Spencer Wells. This description was, however, rejected, and instead it was stated that they were a pair of 5-in. artery forceps with curved ends and a box joint.

The high-light of the examination to me was, however, when a consulting physician attempted (undoubtedly with success) to convince herself that I did not know the difference between chicken-pox and impetigo. This was during an oral examination. I do not know how many cases of either chicken-pox or impetigo the consulting physician had treated in the past ten years, but I have a fair idea of the number I have in the last two years, and as yet I have not used ung. hyd. ammon. dil., sulphathiazole, or penicillin to cure chicken-pox.

I submit, Sir, that the need for carrying out the suggestion put forward in my first paragraph is urgent and that the present system of examining for qualifying degrees is fundamentally unsound. Examiners ought not to be all specialists. The general practitioner is the backbone of the medical profession, and this particular branch absorbs a very high percentage of those obtaining qualifying degrees. Why, Sir, are they then not directly represented on examining boards? If they were it is just possible that less obscure and idiotic questions might be asked, more ordinary common sense might be required from the candidate, and altogether a healthier and more virile type of doctor might be produced.—I am, etc.,

"L.R.C.P.&S."

Diagnostic Acumen of the G.P.

SIR,—There can be no general practitioner, specialist, or consultant who has not made an error in diagnosis during his medical life. The difference is that the G.P. lives in the same town with his mistake, or the relations and friends, and is never allowed to forget it. His mistake teaches him a lot. Not so with the consultant; he gives his diagnosis and appears to

imagine that he is always right. I have had consultations with a large number of "experts" in the last twenty five years, but only one is humble enough to make inquiries later on as to the accuracy of his diagnosis.

If it were the custom, as it should be, not only to write a letter to the consultant on the patient's visit to him but to follow it with a second stating results, I think there would be more bowed heads in Harley Street than in the past. All G.P.s could give many cases of errors by reputable men. I have a patient now who has been seen by five physicians, each of whom has made an entirely different diagnosis, and each now thinks (if he thinks of the case at all) he is an astute physician, but four of the five must be wrong. I do not want to cause embarrassment to many of my friends, and ask to be allowed to sign myself

G.P. SURREY "

International Society of Medical Hydrology

SIR.—It has been decided to hold the first post war meeting of the International Society of Medical Hydrology on Oct 4 and 5 at Buxton, and all local treasurers of foreign countries are being circulated in order to try and obtain a reunion with our colleagues abroad. In addition to the annual business meeting there will be in October a series of papers and demonstrations on hydrology in its application to the rheumatic diseases. Lord Horder has accepted the office of president for the year, our last president in 1939 being the late Sir Farquhar Buzzard. Practitioners wishing further information should get in touch with the local treasurer for Great Britain, Dr Neliean of Droitwich.—We are etc,

J. BARNES BURT
Chairman of Executive Committee
GEORGE D. KERSLEY
Vice-Chairman of Executive Committee

The Disabled Persons Register

SIR.—I am interested in the correspondence on this matter and feel that Dr J. S. Laurie (Feb 2, p 183) has done us a service in opening the question. Although much of what he says has already been adequately answered, I think that more detail may not come amiss, and this might best be expressed in further answers to some of the points raised.

First, although it might appear to an outside observer that many employers act as Dr Laurie suggests, I do not think this is so. It must be remembered that employers are encouraged to help the authorities' efforts to get disabled persons to register under this Act for it is the specific intention to persuade every disabled person in the land ultimately to place himself on the register. This is not so easy as it would seem for there is a marked reluctance on the part of many disabled persons to label themselves as such because it seems to them that by doing so they would reduce their market value as employees. Most employers, in my experience, employ a number of disabled persons (both from the first world war and from industry) and are quite ready to employ more *provided these persons can do the work set them and so earn their pay*. The average employer does not care at all what ailments or deformities a man may have so long as he pulls his weight and maintains reasonably good attendance and punctuality.

Secondly comes the question of the disablement and the Act (Section 1) is quite clear on this point. The disabled person must be 'substantially handicapped in obtaining or keeping employment, or in undertaking work on his own account, of a kind which, apart from that injury, disease, or deformity, would be suited to his age, experience, and qualifications, and the expression 'disablement,' in relation to any person shall be construed accordingly."

There are, however, border line cases, and quite adequate machinery has been set up for dealing with these. When a person applies for registration his claim is carefully scanned by the appropriate Ministry official who is well versed in the Act and its requirements, and, unless the case is quite clear and straightforward, it is referred to one of the district panels. These consist of representatives of the employers, the employees, and of people who are neither and are quite neutral. The panel is advised by a doctor who is paid for his services and has a vote on the panel. The person claiming disablement and whose case is doubtful is first examined by a medical referee appointed by the Ministry, and, in due course is interviewed by the panel

whose members have before them all available information, including the certificate (if any) from the claimant's own doctor and the one from the medical referee. The whole case is then considered by the panel, whose doctor advises them, where necessary, as to the medical evidence, and the claim is then decided. I can assure Dr Laurie that very few frivolous or insufficiently substantiated cases get through. It must be remembered that the panel is answerable to, and works under the direction of, a district advisory committee, again composed of employers' and employees' representatives and of neutral members who are neither the one nor the other. The work is carefully done and carefully checked.

To return to the disabled person. Industries vary, and there is little room for the disabled in some of them while others lend themselves very well indeed to the successful and profitable employment of handicapped people. In the heavy or otherwise unsuitable industries the very limited number of suitable jobs are soon filled so that it is then impossible to do more, and it is here that the register will confer its maximum benefit, for the disabled people who cannot be absorbed into their own industry can be offered suitable work in other industries where they not only can earn their living but can be trusted and valued workers because they have suffered and learned and value their opportunity to justify their existence. If such people are not registered they will simply go on to the scrap heap, as they have done in the past, to become neurotics or embittered misanthropes. I, in common with all industrial medical officers, have repeatedly demonstrated that there are few people who cannot work at something and we have seen numbers of people with well nigh incredible handicaps working successfully at normal occupations and asking no indulgence. The work, however, must be carefully selected, and this means that the people have to be found and classified and the available posts into which they can be put have to be known and listed. Disablement has many surprises, and it sometimes falls out that a man who cannot do light work in one industry finds (sometimes to his own surprise) that he can do quite heavy work in another.

The effort to place handicapped people in proper employment is the main reason which leads the employer and his medical officer (who are encouraged to do so by the authorities) to urge many disabled persons to register. A number of these disabled people work hard and faithfully in circumstances that are bad for them and that need effort which is sometimes heart-breaking. Is it not utter stupidity for them to continue to do so if suitable work can be found for them? It must be remembered that all *substantially* disabled people are eligible whatever be the cause of their disablement, and it seems, to me at any rate, absurd to put them unnecessarily to hardship.

I am entirely in agreement with Dr Laurie when his conscientiousness impels him to insist that the onus of deciding whether a man is sufficiently disabled to be entitled to a certificate should not be placed upon the G.P. Human nature being what it is, there will always be a minority of workers who will want to wangle themselves into something easier than what they are doing and of employers who shirk the effort necessary if they are to give their maximum help in absorbing handicapped people, and the unfortunate doctor in practice may often be exposed to the risk of offending patients and courting unpopularity. I think it would be better if the candidate were referred directly to the Disablement Officer and examined by the Ministry's medical officer, who, of course, should be an experienced industrial medical officer. At the same time it must be remembered that the expert in industrial medicine has his difficulties too. He may know as much as anyone about industry but he knows only as much or as little, of the person's history as that individual chooses or is able to tell him. In many cases it is only the patient's own doctor who can give an opinion which is more than so much waste paper. As an example, is "A" really an epileptic? How often and severe are his fits? Does he wet himself in his fits? Are there any post epileptic sequelae? Is he in the early stages of degeneration? How much narcotic is he taking? How am I, for instance, to find out on one examination? Examples could be multiplied *ad nauseam*.

I would suggest, therefore, that the man's own doctor *must* be in the picture in a goodly proportion of cases. The objection, of course, is that the unfortunate G.P. already fills up all the medical forms which an industrious bureaucracy has devised to

date, and nobody sees any prospect of a stop in the steady flow of unpaid clerical work that flows in upon him. He should get a fee for his certificate, and the result of this, I think, would be, as I have already suggested, that the disabled person would be instructed to apply direct to the Disablement Officer, who would refer him to the medical referee. In cases in which the medical attendant's opinion was important or necessary his views would be requested and he would be paid for his advice.

It is intended under the Act to "designate" certain forms of employment, which means that these designated vocations will be set aside for disabled people, and that it will be illegal for an employer to give such work to a fit person unless and until there are no disabled people readily available. To my mind this is wholly good and will go a long way, not only to preserving the self-respect and material prosperity of a class of people who really need help, but also to checkmating the activities of that small but noisome minority of lazy and unscrupulous people who trade upon the laws designed to help the unfortunate, and who thus bring undeserved discredit and annoyance to their fellow workmen, who regard them and their practices even less kindly than I do. Equally it would make it impossible for that similarly small and unpopular corresponding group of employers to evade some, at least, of their responsibility.

The Act lends itself to modification and development (by Statutory Regulations and Orders and by memoranda, or even, later on, by amendment in Parliament), and it is possible to foresee a time when its provisions will be available to that class of people who, while not being "substantially handicapped" within the present meaning, are yet so affected by disease, injury, etc., as to be at a serious risk or handicap in the employment they follow. Numerous examples will occur to any G.P. of experience, and a little reflection will satisfy anyone of the tremendous possibilities opened by such a development in the cure and rehabilitation of that large group of the chronically sick whose conditions depend largely on various physical environmental maladjustments, and who, at present, are unable to avail themselves, except at the cost of their jobs, of the fullest opportunities of expediting their recovery or, alternatively, of preventing steady deterioration of their health.—I am, etc.,

Wear Shipbuilders' Association, Sunderland.

A. REFALAS.

The Metric System

SIR.—Perhaps I am trying to infuse fresh blood into a stale corpse, but your annotation (Jan. 5, p. 19) prompts me to make the attempt.

Pro.—The metric system is international.

Con.—When the Basle Nomenclature was introduced into anatomy about 1909 the same argument was used, the advocates never realizing that it was far more important for students to understand their own professors than for the latter to understand some erudite gentlemen in Basle or Berlin. Result, the unhappy student had, and I believe still has, to learn two systems of nomenclature, and the confusion still persists, "which," to quote your annotation, "is a sobering thought."

Pro.—The metric system is scientific.

Con.—We all know the therapeutic value of the apparently mystic symbols in our prescriptions, and it would be a thousand pities to destroy the public faith in this mystery by replacing our signs with something "understanded of the people." Change aqua menth. pip. to aqua chloroformi, and the patient will complain that "the new medicine is not the same as the old," the implication being that it is not so good. In this Eastern land, where faith abounds, I have even had a zealous patient swallow the prescription with both relish and apparent benefit.

Pro.—The metric system is easily remembered.

Con.—Perhaps it is in the larger doses, but what about the small? We can imagine a busy practitioner inadvertently misplacing a decimal point, or even waking in a cold sweat at 3 a.m., thinking, "Hyoscine, I know the dose is a two-hundredth of a grain, but is it 0.0003 of a gramme or 0.003? Is it 0.3 or 0.03 of a milligramme? Shades of Dr. Crippen, I must have poisoned the woman!"—I am, etc.,

H. WILLIAMSON,
Lieut.-Col., I.M.S.; Surgeon to
H.E. the Viceroy.

New Delhi.

Obituary

RALPH STOCKMAN, M.D., LL.D.

Ralph Stockman, emeritus professor of materia medica and therapeutics in the University of Glasgow, died in his eighty-fifth year on Feb. 27. Born in 1861 at Leith, the son of W. J. Stockman, a merchant in that town, he was educated at the Royal High School, Edinburgh, from which he proceeded to the study of medicine at the University of Edinburgh. After graduation in 1882 he spent two years at the Universities of Vienna and Strasbourg before returning to Edinburgh. In 1886 he obtained the degree of M.D. with high distinction, being awarded a gold medal for his thesis. He became a member of the Royal College of Physicians of Edinburgh, of which he was elected a Fellow in 1889. From his student days he was interested in the actions of drugs, and on his return to Scotland from the Continent began his life work in the teaching of pharmacology or, as it is called in Scotland, materia medica. First as an assistant in the University department at Edinburgh and then as a lecturer in the extramural school of medicine he established a reputation as a teacher which was enhanced after his appointment in 1897 to the chair of materia medica in the University of Glasgow. This appointment he held till his retirement in 1936. In the following year the degree of LL.D. *honoris causa* was conferred on him.

From his early days Stockman emphasized the importance of correlating pharmacological work with clinical experience. It was not therefore surprising that on his arrival in Glasgow he was appointed a physician to the Western Infirmary. In the following year he was elected a Fellow of the Royal College of Physicians and Surgeons of Glasgow. In Glasgow he exerted a profound influence on the development of the medical curriculum. During his tenure of the chair there was a great expansion in facilities for the teaching of the basic sciences, and his own department was greatly enlarged. In the conduct of his classes in the lecture-room, laboratory, and above all in the clinic he held to the view that the most important function of the teacher is to separate the grain from the chaff. Inevitably during a period when pharmacology was slowly being established as a science, his teaching tended towards scepticism which perhaps rather overwhelmed those who liked to lean on authority. The stronger minds, however, were infected by the enthusiasm of one with a full personal knowledge and with a sense of obligation to contribute to the sum total of human knowledge. They felt that they were in the presence of one with the viewpoint of Locke that the purpose of education is to "get a relish of knowledge." Throughout his teaching he stressed the importance of the historical outlook, without which one's appreciation of any problem, social or scientific, is limited.

For Stockman the study of disease began with the patient. As physician and clinical teacher he showed outstanding clinical acumen combined with an appreciation of the sick person as an individual possessed of hopes and fears and as a member of the community having social obligations. To take part in a ward round with Stockman was an experience never forgotten. He used the Socratic method of instruction and his remarks were illuminated by his vast personal experience, his knowledge of literature both medical and general, and his great critical faculty. He possessed those qualities of mind described by Hippocrates as indispensable for a physician—learning, sagacity, humanity, and probity. Throughout his career he was engaged in investigation, and his published papers include work on the coca alkaloids, the camphor group, the arrow poisons, lathyrism, and many other subjects. Worthy of special mention are his contributions to the pharmacology of iron and to the aetiology and treatment of chlorotic anaemia. This work has stood the test of time, to be confirmed by recent investigations with modern analytical methods. During his stay in Glasgow he became specially interested in the study of the chronic rheumatic diseases, and based on the results of this work is his monograph on *Rheumatism and Arthritis* published in 1920. This, a model of clear thinking and lucid writing, has done much to get rid of many useless beliefs, an essential prerequisite for scientific

work. In the words of Osler he believed that "to the physician a scientific discipline is an incalculable gift which leavens his whole life, giving exactness to habits of thought and tempering the mind with that judicious faculty of distrust which can alone amid the uncertainties of practice, make him wise unto salvation."

Throughout his occupation of the chair at Glasgow he took an active part in the communal life of the university. He was specially interested in the life of the students and for many years was senior vice president of the Union, which benefited greatly from his wise and kindly supervision. Among students he achieved a great popularity. Perhaps somewhat afraid of his wit, which at times was keen, they always came to realize that in Ralph they had someone who, realizing their weaknesses, was zealous in their defence and for their welfare. Many Glasgow graduates all over the world will hear with regret of the passing of one of the great figures of their student life.

After his retirement in 1936 he moved to Edinburgh but still took an active interest in friends and affairs. Till the very end there was no lack of mental energy and the freshness and pliancy of his mind did not for a moment fail. He is survived by his sister, to whom he owed much and who was his companion and counsellor, acting as hostess and endearing herself to all who know her by her wisdom, wit, and charm. Of Ralph Stockman one might say that he

'Loved no darkness,
'Sophisticated no truth,
'Nursed no delusion,
'Allowed no fear."

N M

Prof. Stockman had joined the British Medical Association as long ago as 1884 was awarded a B.M.A. scholarship in 1886, held office as vice-president of the Section of Pharmacology and Therapeutics at the Edinburgh Meeting of 1898 and as president of that Section of the Belfast Meeting in 1909. At headquarters in London he served on the Science Committee, on the Standing Therapeutic Subcommittee set up in 1919, on the Organization of Medical Students Subcommittee, and on the Medical Students and Newly Qualified Practitioners' Subcommittee.

W S A GRIFFITH, CBE, MD, FRCP, FRCS

'Dr W S A Griffith lived long enough to become the patriarch of his branch of medicine. After many years in retirement at Chelsea and later at Haslemere he died peacefully on Feb. 26 at the age of 91. He had been consulting physician accoucheur to St Bartholomew's Hospital since 1919, when he resigned from the active staff, and he was also consulting physician to Queen Charlotte's.

Walter Spencer Anderson Griffith was born at Brighton in 1854 and went to school at Brighton College, where his father, the Rev. John Griffith, LL.D., was headmaster. His younger brother, F. L. Griffith, D.Litt., professor emeritus of Egyptology in the University of Oxford, died twelve years ago. Walter Griffith began his medical study at the Royal Sussex County Hospital, Brighton, and went on to St. Bartholomew's, qualifying as M.R.C.S. in 1878, and after holding house appointments obtained the F.R.C.S. in 1881. Deciding to take degrees at Cambridge he entered Downing College and kept the statutory nine terms by sleeping at week-ends at Cambridge while he lived in London. He graduated M.B. in 1885 and proceeded M.D. in 1889, and was elected F.R.C.P. in 1893. The decision to devote himself to obstetrics and gynaecology had been taken in the early 'eighties, and his outstanding ability secured the posts of physician-accoucheur to the Great Northern Hospital, teacher of midwifery at St. Bartholomew's, physician to out-patients at the Samaritan Hospital for Women, and physician to Queen Charlotte's Lying-in Hospital. At that time James Matthews Duncan was at the height of his fame in London. On Duncan's death in 1890 Francis Champneys was recalled from St. George's Hospital to take his place as head of the obstetric department at St. Bartholomew's and Walter Griffith was made physician accoucheur with charge of out-patients. The chief things that Sir Francis Champneys and Dr. Griffith (colleagues for many years) had in common were their devotion to the memory and teaching of Matthews Duncan and their fondness

for music. Griffith succeeded Champneys in the senior post, and on retiring under the age limit at 65 was elected consulting physician accoucheur, a governor of the hospital, and a member of the house committee. He was also consulting gynaecologist to the Queen Alexandra Military Hospital, Millbank. He examined in midwifery for the Royal College of Physicians of London in 1893-7 and served on its Council in 1914-16, he represented the Royal College of Surgeons of England on the Central Midwives Board. He had joined the B.M.A. in 1880 and held office as secretary of the Section of Obstetric Medicine at the London Meeting of 1895 and president of the Section of Obstetrics and Gynaecology in 1900 at Ipswich, he had also been president of his section at the Royal Society of Medicine. He was created C.B.E. for his services during the war of 1914-18, and the Medical Defence Union made him president in 1932.

Dr. Griffith enjoyed teaching and mostly used the Socratic method. Bart's men of a former generation will call to mind his mornings in the shabby little out-patient room of those days, the tall central figure topped by a black velvet skull-cap and perched on a high stool, one hand pointing with a uterine sound to the student chosen for ironic interrogation, while beside the couch stood a nurse guarding the shrouded patient from the packed audience. Much was learnt at those clinics, but few could stand up long to the master's flow of questions without loss of composure, though a legend survives that one habitual wag, after angling for the dunce's chair, gave a tit-for-tat.

Now, Mr. Black, suppose I have tried all the interesting things you tell me to do in this emergency and have failed. What do I do next?" "If I were you, sir, I would send for Dr. Champneys." History does not say if Dr. Griffith joined in the laughter, but he had a sense of fun beneath a formidable manner. His lucid and practical teaching, both at St. Bartholomew's and at Queen Charlotte's, was eagerly sought and gave a long line of students their groundwork in the art of midwifery.

DAVID RORIE, D.S.O., M.D., C.M.

Dr. David Rorie, one of the most distinguished post-physicians of Scotland, died on Feb. 18 in his 79th year. He had long been established in practice in Culter, but had retired from the active work of his profession in 1933. At the outbreak of the present war, though full of years, he was anxious to render what service he could and continued to serve on medical boards till within a few months of his death.

He received part of his preliminary education in the Aberdeen Collegiate School and later matriculated at Edinburgh University, where he graduated M.B., C.M. in 1890, and in 1908 proceeded to the degree of M.D. In 1911 he took his D.P.H. with honours in the University of Aberdeen. After graduation he spent some years in general practice in the mining districts of Fifeshire, a period of his life to which he frequently referred, and in that work he laid the foundations of that deep understanding of human nature and sympathy with the underdog which was so characteristic of him in his later years, and which so deeply coloured his life's work both in medicine and in literature and is expressed so poignantly in some of his more serious poems.

At the outbreak of the first world war he was mobilized as a captain, R.A.M.C.(T.F.), but was rapidly promoted to major in 1915, and lieutenant-colonel in 1916, acting as O.C. 1/2 Highland Field Ambulance. Later he became full colonel and acted as A.D.M.S. to the 51st Highland Division, with which he served throughout the war. For his services he was awarded the D.S.O. in 1917 and in 1918 was made a Chevalier de la Légion d'Honneur. In addition he became the unofficial poet laureate of the 51st and was reported to be the anonymous author of many of the famous marching songs of that division, though to this he would never admit. In 1929 he published his own reminiscences in a volume *A Doctor's Luck in the War* which recounts the medical history of the gallant 51st. In the first chapter his satirical humour is given full scope and he recounts with gusto many a good story of the Colonel Blanks of that generation. Throughout his life he maintained his interest and affection for the ex-Service men and became one of their doubtless champions. Largely due to his efforts the local branch of the British Legion was founded, of which he was the president from 1922 onwards, as well as serving on the national council. His years in France remained for him a

happy memory, since, perfervid Scot as he was, he had an intense interest in the French—their history and their culture as well as a considerable knowledge of and facility in their language and literature—and to him it was historically appropriate that the 51st should be serving in the fields of France, for that was but a modern continuation of the "Auld Alliance." In the post-war years he remained an active member of the Franco-Scottish Society.

He took his full part in the communal life of the profession, a regular and enthusiastic member of the Aberdeen Medico-Chirurgical Society, and a loyal member of the British Medical Association, being chairman of the Aberdeen Division 1924-9 and president of the Branch 1932. At the Annual Meeting of the Association in 1914 he was honorary secretary of the Section of Medical Sociology and, for the 1939 meeting, editor of *The Book of Aberdeen*. He was much in demand as an after-dinner speaker, an art in which he was highly proficient. At the annual dinner of the Medical Society he generally contributed a poem composed for the occasion, in which, with great good humour and wit, he satirized the foibles and failings of his best friends and of medicine generally, all in the classic tradition of François Rabelais.

Deeply interested in folk lore and folk medicine he contributed many articles on these and kindred subjects to the *Caledonian Medical Journal*, the *Edinburgh Medical Journal*, the *B.M.J.*, and other lay and medical magazines. "Folk Lore of Mining Folk of Fife," one of the earliest, was published in the Folk Lore Society's County Series. For many years he was editor and later joint editor of the *Caledonian Medical Journal*. His own two volumes of poems, *The Auld Doctor*, 1920, and *The Lum Hat Wantin' the Croon*, and other Poems, 1935, were known to all Scotsmen and were sung or recited in all parts of the world where Scotsmen foregather. Perhaps his very facility in the use of the Scotch vernacular and his sparkling wit and humour were not altogether an advantage in that they tended to obscure the beauty of his more serious poems such as "Daylight has Mony Een" with its unforgettable last verse. In the preface to *The Lum Hat Wantin' the Croon* he gives his own too modest estimate of his poetry, where he describes himself as "leaving a gangrel's stance on the lower steps of Helicon."

Perhaps to those who loved him—and they were legion—the St. Andrew's Cross which formed his pall and the wreath of Flanders poppies were fittingly symbolic of the life and achievement of that serene and radiant spirit that was David Rorie.

A. GREIG ANDERSON.

David Rorie occupies a place of his own in modern Scottish letters. For over fifty years he has been known to Scotsmen and the friends of Scotsmen all over the world as the author and composer of the "Lum Hat Wantin' the Croon," a rollicking, humorous ditty which has probably been sung at more convivial entertainments than any other contemporary lyric. Unfortunately, while the "Lum Hat" made Rorie famous, in its way it did him some disservice by identifying him rather more closely than his talent and his philosophy warranted with the farcical and the extraordinary in verse. He certainly was the author of a long string of exceedingly funny songs like the "Pawky Duke," "Macfadden and McPhee," "The Speeshalist," and many more of that kind which, although a great deal of sense goes through the comedy, can hardly be expected to be remembered except as outbursts of high spirits. Rorie, however, could when he liked go better and deeper than that, and he wrote some lovely little pieces like, for example, "Daylight has Mony Een" in his younger days and some refreshingly sharp satire like "Neebors" and the "Obituary Notice" in his later years.

Many of his songs have not appeared in print, and some, though in print, are not easily accessible. He wrote for his friends and he wrote for social occasions, and during the 1914-18 war he was the author of many a camp-fire ballad that helped to keep up the hearts of the troops in miserable surroundings. Sometimes he wrote in English, but mostly his medium was the Scots dialect, which, though perhaps it hampered the full expressions of his philosophy because of its lack of words, at the same time imparted a raciness and a downright quality to his lines which in Scotland and among Scotsmen made them very memorable indeed!

A. K.

The following well-known medical men have died abroad: Dr. MARC TIFFENEAU, professor of pharmacology and materia medica in the Paris faculty of medicine, member of the Académie de Médecine and Académie des Sciences, aged 72; Prof. G. JEANNENEY, head of the departments of clinical surgery and gynaecology at Bordeaux; Prof. LÉON SRIÉNON, an eminent pathologist at Brussels, aged 95.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Sir Howard W. Florey, M.D., F.R.S., professor of pathology in the University of Oxford, has been elected into an Honorary Fellowship at Gonville and Caius College, of which he was formerly a Fellow.

At a Congregation held on March 1 the following medical degrees were conferred:

M.D.—*C. Maynard Heath.
M.B., B.Chir.—D. A. G. Galton, A. C. Arthur, E. Ellis, J. S. R. Golding, R. H. Ellis, S. M. Hilton, *M. D. King.

*In person.

UNIVERSITY OF EDINBURGH

The Court of the University of Edinburgh and the Corporation of Edinburgh have appointed Mr. Andrew Logan, F.R.C.S., surgical registrar at the Royal Infirmary, Newcastle-upon-Tyne, to the combined post of lecturer in thoracic surgery in the department of surgery of the University and thoracic surgeon to the municipal hospitals of the Corporation.

UNIVERSITY OF GLASGOW

During April and May a series of postgraduate lectures in ophthalmology will be given in the Department of Ophthalmology of the University on Wednesdays from April 3 to May 8, both dates inclusive, at 8 p.m. The meetings will be open to all medical practitioners and senior students interested in ophthalmology. Details will be published in the diary column of the *Supplement* week by week.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following surgery lectures will be delivered at the College at 5 p.m. on each day: April 1, Sir Heneage Ogilvie, "Inguinal Herniae"; April 3, Prof. John Morley, "Surgery of the Stomach"; April 4, Mr. R. Maingot, "Surgery of the Spleen"; April 8, Mr. L. E. C. Norbury, "Surgery of the Rectum, with Special Reference to Malignant Disease"; April 10, Prof. H. J. Seddon, "Peripheral Nerve Lesions"; April 11, Sir Gordon Gordon-Taylor, "Surgery of the Colon"; April 15, Mr. W. Rowley Bristow, "Joint Injuries"; April 16, Mr. E. W. Riches, "Surgery of the Prostate"; April 17, Mr. V. E. Negus, "Injuries of the Ear, Nose, and Throat"; April 24, Mr. J. B. Hunter, "Surgery of the Heart"; April 25, Sir Reginald Watson-Jones, "Fractures of the Pelvic Girdle"; April 26, Mr. T. Pomfret Kilner, "Pedicule Grafting." Fellows and Members of the College will be admitted free. A fee of 3 guineas for the course will be charged in the case of others. Tickets may be obtained on application to the Secretary of the College, Lincoln's Inn Fields, W.C.

The Services

Sir Alfred Webb-Johnson, Bt., President of the Royal College of Surgeons of England, has been appointed chairman of the Army Medical Advisory Board in succession to the late Viscount Dawson of Penn.

Col. (Temp. Brig.) F. Harris, C.B.E., M.C., late R.A.M.C., has been appointed Honorary Surgeon to the King in succession to Major-Gen. D. T. Richardson, C.B., M.C., late R.A.M.C.(ret.); and Col. (Temp. Brig.) H. A. Sandiford, M.C., late R.A.M.C., Honorary Physician to the King in succession to Major-Gen. L. T. Poole, C.B., D.S.O., M.C., late R.A.M.C.(ret.).

CASUALTIES IN THE MEDICAL SERVICES

Died on Sept. 27, 1945, by misadventure while carrying out research work at R.A.F. Station, Nijmegen.—Fl. Lieut. Donald Archibald Stickland, R.A.F.V.R.

Died.—Major Ian Donald Cruickshank Veitch, Capt. Bruce Carstairs Jeffrey, R.A.M.C.

Died in Greece as the result of an accident.—Capt. John Vaughan Shepherd, R.A.M.C.

Fl. Lieut. (Acting Squad. Ldr.) WILLIAM MCKEE BONNAR died on Feb. 25 of injuries received in a flying accident in India. He was born in 1917, studied medicine at Queen's University, Belfast, and qualified M.B., B.Ch. in 1939. He was demonstrator in physiology at Queen's University until commissioned in the Medical Branch, R.A.F. Volunteer Reserve, in October, 1941.

Medical Notes in Parliament

Industrial Injuries: A New Committee

The National Insurance (Industrial Injuries) Bill was read a third time without a division in the House of Commons on Feb. 22. In a closing speech Mr. JAMES GRIFFITHS said the Bill had been criticized because it did not provide compensation for nurses who contracted tuberculosis at their work. It did not specify a list of industrial diseases or of workmen who were entitled to claim. Clause 54 was sufficiently wide for him to schedule tuberculosis contracted by health workers if the evidence was strong enough. In the past the task of scheduling industrial diseases had been easier than it would be in the future. Miners' nystagmus, for instance, was fairly easily recognizable. But the Ministry of National Insurance was now reaching the stage where it was not easy to draw the line between disease which was constitutional or arose from natural causes, and the disease arising from industrial causes. That was becoming difficult because mechanization and speeding up were bringing a new range of problems and industrial diseases. A group of 'neurotic diseases' would have to be considered. He proposed, therefore, to set up a committee of persons, both medical and lay, to recommend some criteria which would help the Minister to decide the dividing line in these cases. At the moment he was considering the nurses' claim and also one for Raynaud's disease, which had suddenly come into prominence. It was claimed that in one factory scores of cases of this disease were due to the effect of vibratory tools on the hand.

Mr. HOUSE remarked that Mr. Griffiths had not referred to the right of the injured workman to preserve his freedom of choice of practitioner.

Mr. GRIFFITHS said he could not be expected to pronounce on that. Soon the House would consider proposals for a new health service. Mr. House's question would be much more relevant then. The matter must be dealt with in a general way and not as confined to the Industrial Injuries Bill. In conclusion Mr. Griffiths said the number of preventable accidents was still far too high. So was the number of industrial diseases which could be prevented. In South Wales alone the number of persons disabled in one year by pneumoconiosis and silicosis exceeded 5,000.

Pay of Service M.O.s

A White Paper proposing new rates and conditions of pay and allowances for officers in the Navy, Army, and Air Force has been submitted to Parliament. It does not apply to the medical or dental services. Further consideration is being given to the positions of these, but the decisions on them are not contingent on the Government's proposals for a National Health Service.

Medical Services in Singapore

Mr. H. STEWART on March 1 referred to the lack of health and hospital services in Singapore. He asked what the Secretary for the Colonies was doing to make available in Singapore the hospital accommodation now in occupation by S.E.A.C., and what progress was being made in recruiting European staff for the medical service.

Mr. CRECH JONES said the present administration was working strenuously to restore these services in the face of difficulties. It should be possible to announce soon the date of handing over from military to civil administration. A board had been set up in Singapore to ensure the speediest return by the services of civil property. A high priority would be accorded to hospitals. Medical officers who had been interned were returning as they became fit for a short tour of service. In addition a number of doctors had been or were being selected for appointment to the Colonial Medical Service for duties in Malaya. Others had been engaged on short-term contracts supply of medical equipment was steadily going forward.

Austrian Doctors at Home and Abroad

Col. STODDART SCOTT inquired on March 4 how many doctors of Austrian nationality who had been given a licence to practise were still in this country. Mr. BEVAN replied that a completely up-to-date figure was not readily available, but in November last the number of Austrian doctors in this country who were in the *Medical Register* was approximately 230. He did not now how many had returned to Austria since VE-Day.

On March 6 Col. STODDART SCOTT asked how many doctors here were 1,000 of the population in the British zone of Austria, and how many doctors in Vienna compared with pre-war. Mr. J. HYND replied that in the British zone of Austria

the average worked out at 0.934 per 1,000 of the population as compared with 0.816 before the war. In the city of Vienna there were to-day some 2,800 doctors compared with 4,100 before the war. Taking into account the decrease in population, the proportion of doctors had been only slightly reduced. The figures for the pre-war period in the zone were one doctor per 1,225 of the population and to-day one doctor per 1,070 of the population. In Vienna there was one doctor for every 468 of the population pre-war, and to-day one doctor to every 521.

Atomic Research in Britain

Mr. ATTLEE announced on March 5 that the programme of atomic research in this country was not limited by financial considerations but by the numbers of trained scientists and the material resources available, especially in building and engineering equipment. Within these limits this programme of research was being developed as rapidly as possible. Expenditure on it for the year 1946-7 was estimated at approximately £2,800,000.

Medical Care of Colonial Civil Servants

Squad Ldr. DUNN asked on March 6 whether members of the Colonial Civil Service invalidated home or having to undergo medical treatment while on leave could obtain financial help towards the cost of treatment when this was necessitated as a result of injury or disease contracted in the course of duties in the colony. Mr. CRECH JONES said it was the practice for Colonial Governments to pay the fee for an examination by a consulting physician together with any expenses incurred in the diagnosis of the officer's complaint. Except for those on very low salaries, Colonial civil servants were not entitled to free treatment in this country, but could get treatment including operations, at special rates under arrangements made with the Seamen's Hospital Society and the Royal Infirmary, Liverpool. Colonial Governments were usually willing to give sympathetic consideration to applications for assistance from officers whose medical expenses were unduly burdensome.

Hospitals in the National Health Service

On March 7 Sir P. MACDONALD asked whether the Minister of Health intending to include the voluntary hospitals in his legislative proposals for nationalizing the medical profession, and if he would make their position clear so as to enable these hospitals to make plans for the future. Mr. BEVAN said the Government's proposals for a National Health Service could be submitted to the House as soon as possible. He did not think he ought to anticipate them in any way at that stage.

Medical News

The Royal Society of Medicine has arranged a series of special meetings on practical problems which faced medical science during the war. They will be held from March 18 to 22, and March 25 to 29, at 1, Wimpole Street, at 5 p.m., the first week being devoted to problems of protection, and the second to problems of efficiency. The subjects of the first half of the series are: March 18, cold and heat, with Sir John Anderson in the chair; March 19, burns, B.A.L., ruses, and blast, with Sir Henry Dale in the chair; March 19, acceleration, with Viscount Falmouth in the chair; March 21, applications of anatomy and physiology, with Prof. E. Le Gros Clark in the chair; March 22, diseases in the field, with Lieut.-Gen. Sir Alexander Hood in the chair. During the second week problems of efficiency will be discussed, as follows: March 25, visual and auditory, with Sir Ernest Rock Carling in the chair; March 26, psycho-logical, with Sir Lionel Whitby in the chair; March 27, respiratory, with Sir Henry Tudor in the chair; March 28, nutritional, with Sir Frederick Lenth-Ross in the chair; March 29, restoration of efficiency, with Lord Horder in the chair. Fellows of the R.S.M. may be admitted without ticket, Fellows bringing guests should apply to the Secretary of the Society for admission tickets for their guests.

A joint meeting of the Microbiological and Nutrition Panels of the Food Group of the Society of Chemical Industry will be held on Wednesday, March 20, at 6.20 p.m. in the rooms of the Chemical Society, Burlington House, Piccadilly, W., to discuss a paper by Dr. E. C. Barton-Wright on amino acids and the metabolism of the cell.

Our obituary notice of Mr. Robert Weir, F.R.C.S., of Exeter, published on Aug. 25 mentioned that besides being one of the best known surgical specialists in the West of England he was also a man of more than local fame as an accomplished water-colour painter. During the last twenty years of his life he developed his native skill with the brush and devoted much of his leisure to water-colour. A memorial exhibition of his works is to be held in London at the rooms of the Fine Art Society in Bond Street, W., starting on Wednesday next, March 20.

The Lord Mayor of London took the chair at the 73rd annual general meeting of the Metropolitan Hospital Sunday Fund, held at the Mansion House. Mr. C. J. Holland-Martin, vice-president, said that they were anxiously awaiting the announcement of the Government's plans for the hospital system of the country. In the meanwhile there was danger that, in the uncertainty about the future, the immediate needs of the patients might be forgotten. Money would be needed by the hospitals in the interval before any new scheme could come into effect.

Workers in the motor-car branches of the Nuffield organization are being asked to take part in research to be conducted by Prof. J. A. Ryle, Fellow of Nuffield College and Director of the Institute of Social Medicine at Oxford, into the causes of gastric and duodenal ulcers.

At the meeting of Senate of the Queen's University of Belfast on Nov. 21, 1945, Mr. C. H. G. Macafee, F.R.C.S., was appointed Professor of Midwifery and Gynaecology. Prof. C. G. Lowry, F.R.C.S., who was appointed Professor of Midwifery in 1920 and Professor of Midwifery and Gynaecology in 1937, was accorded the rank of Emeritus Professor.

Mr. E. Stanley Evans, M.B., B.S., F.R.C.S., has been appointed medical superintendent of the Lord Mayor Treloar Cripples' Hospital and College, Alton, Hants, and took up his duties there on March 5. Mr. Evans was previously medical superintendent of Queen Mary's Hospital for Children, Carshalton.

At a meeting of the Royal Society of Edinburgh, held on March 4, the following members of the medical profession were elected Fellows of the Society: Prof. Daniel Fowler Cappell, M.D., Hugh Shaw Dunn Garven, M.D., Prof. Stuart M'Donald jun., M.D., and Prof. Richard Loraine de Chasteneay Holbourne Saunders, M.D.

Sir Drummond Shiels, M.B., is a member of the committee appointed by the Prime Minister to "consider the future of the terraces adjoining Regent's Park from all aspects, architectural, town planning, and financial, and to make recommendations as to their future adaptation, or replacement, to meet modern requirements."

It is announced that Bournemouth Council is to take over the U.S. Army hospital at St. Leonards, near Ringwood in the New Forest, consisting of huts, for use till a permanent hospital can be provided.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a further fall in the notifications of acute pneumonia (262), but other infectious diseases increased in prevalence. The rises included whooping-cough 303, dysentery 151, measles 98, diphtheria 21.

The largest falls in pneumonia were Lancashire 79, Middlesex 54, Warwickshire 35. Cases of diphtheria showed increases in Lancashire 19 and London 10, and a decrease of 12 in Yorkshire West Riding. The only county with a marked increase in the notifications of measles was Lancashire 61. The rise in whooping-cough was greatest in Yorkshire West Riding 86, Lancashire 38, Middlesex 34. The only marked fluctuations in the local returns of scarlet fever were increases in Lancashire 39 and London 26.

Notifications of dysentery increased in many areas. The only new outbreak during the week was in Hertfordshire, Bushey U.D., where 74 cases were notified. Other large returns were: Lancashire 54, Leicestershire 30, London 29, Northumberland 22, Bedfordshire 17, Worcestershire 15, Middlesex 14, Northamptonshire 14, Essex 14, Yorkshire West Riding 14, Norfolk 13, Warwickshire 13, Gloucestershire 12.

In *Scotland* fewer cases of primary pneumonia (91) and scarlet fever (42) were notified, while an increase was recorded for measles 201, diphtheria 21, and dysentery 21. The chief centres of dysentery were the cities of Glasgow 12, Dundee 12, and Edinburgh 10.

In *Eire* there was a rise in pneumonia (59), and in enteritis and diarrhoea (17). In both instances the rise was due to the experience of Dublin C.B.

Scotland's Birth Rate

The preliminary returns for 1945 show that the birth rate of 16.9 per 1,000 was the lowest ever recorded; the previous lowest was 17.1 in 1940. The infant mortality was 56 per 1,000 live births, and the maternal mortality reached a new low level at 2.9 per 1,000 live births.

Week Ending March 2

The notifications of infectious diseases in *England and Wales* during the week included: scarlet fever 1,232, whooping-cough 1,605, diphtheria 501, measles 1,583, acute pneumonia 860, cerebrospinal fever 70, dysentery 323, paratyphoid 23, typhoid 8. Five of the eight cases of smallpox were imported. There were 123 deaths attributed to influenza in the great towns.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Imported case.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: A.M.C.O. If possible, the original articles and letters forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publisher, Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proof. Authors overseas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: Articulate W.E.S.E.C. London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: Med. Sec. W.E.S.E.C. London.

B.M.A. SCOTTISH OFFICE: 22 Drumhugh Gardens, Edinburgh 3.

ANY QUESTIONS?

Chronic Villous Synovitis

Q.—A woman aged 45 has had a chronic synovitis of the right knee for ten months. X-ray examination shows no bony change, but some thickening of synovial membrane is now evident. What is the condition and what the cure and would a biopsy prove anything?

A.—The case appears to be a chronic villous synovitis of the type to which women at or near the menopause seem to be especially susceptible. The condition is often very resistant to treatment, but tends to pass into osteoarthritis which is not usually of a severe type and with this change acute pain gives way to slight stiffness and crepitus on movement. While endocrine factors may have a predisposing influence, it is doubtful if they have any causative effect and when one joint only is affected a slight strain is the most usual direct cause. Careful investigation should be made for any infective focus or source of toxic absorption particularly in the pelvis and alimentary canal, and the blood ureic acid might be estimated to exclude chronic gout. It is important to support the joint and to avoid long standing and any unnecessary movement: a blocked leather knee cap or a Howard Marsh cage splint might be worn with advantage for a few months, the joint should be moved through the full range morning and night to guard against the formation of adhesions. Drug treatment is of doubtful value but a combination of iodine and thyroid might be useful and full doses of vitamin C have been advised. Locally, ionization with potassium iodide may help. If these measures are ineffective and the symptoms are severe enough to demand more drastic treatment the opinion of an orthopaedist should be sought as to the expediency of synovectomy, which is practised in the U.S.A. more often than in this country and, it is claimed, with good results.

Nail Growth and Nail-biting

Q.—What are the factors governing the growth of the finger nails? Is there any method whereby such growth can be speeded up? What are the best methods to stop nail biting in a child who seems to have a peculiar liking for aloes and other deterrents?

A.—The growth of the nails, like that of epidermis and hair, is governed by the vascular and nervous control of the part. On an average nails grow about 1/8 in. (3 mm.) a month, but there is variation between individuals and in the same individual, depending upon variations of health. Growth cannot be influenced by drug treatment, though x-ray therapy locally appears sometimes to retard it. I know of no method of increasing the rate of growth.

Nail biting has nothing to do with nail growth and is a problem in psychological medicine, though commonly of no major significance. The temperament and environment of the child and the make up and attitude of the parents probably call for attention and a child guidance or psychiatric expert might be consulted. A minor disturbance may start what becomes merely a bad habit and it is probably wise to avoid giving the matter undue prominence and wasting time on local treatment to the nails which may only increase the child's desire to bite them. (See also answer given on March 24, 1945 p. 432.)

Oedema in a Hemiplegic Limb

Q.—A woman of 61, who has had varicose veins and a poor circulation all her life had a thrombus of the uterine capsule seven years ago causing paralysis of her left side. Since then she has had swelling and oedema which disappears on lying down of the left foot and leg. Massage helps it but produces no permanent benefit. What treatment should be adopted?

A.—Oedema in a hemiplegic limb is usually due to mechanical immobility and retarded venous circulation. The presence of varicose veins would enhance the tendency to oedema and there is of course the possibility of an associated thrombosis of one of the veins of the leg. No active treatment is indicated, but the patient should prop the foot up when resting in a chair. The massage to the limb should be accompanied by passive and if possible active movements of the ankle and knee joints.

Trench Mouth

Q.—What is the best treatment of so-called trench mouth?

A.—Experience earlier in the war led workers to concentrate on the treatment of trench mouth by local measures. For this purpose a 20% solution of chromic acid was used, followed by the application of 20 volume hydrogen peroxide. For sub-acute cases and for the later stages of the acute cases packing between the teeth with a paste of zinc oxide and oil of cloves was most effective. Recently, however, it has been shown that the spirochaetal infection of the mouth and throat which is responsible for trench mouth can be completely overcome in the great majority of cases by intramuscular injections of penicillin, 100,000 units a day for three days or less with or without the use of mouth washes of hydrogen peroxide. It is probable therefore that the ideal treatment for trench mouth is a short course of systemic administration of penicillin plus subsequent dental treatment to clear up gingival flap, caries, malocclusion, etc.

Causation of Schizophrenia

Q.—In Huntington's chorea when an affected female marries a normal male only 33% of the children have the disease instead of 50% in the remaining 15% the necessary determining circumstances are not there. In schizophrenia many who are believed to possess the hereditary tendency do not develop the disease owing presumably to lack of determining factors. This implies that hereditary potentialities may be dormant throughout life or may be precipitated only by appropriate influences. At the age of 30 a patient whose personal and family history was good with no evidence of mental disorder had to leave his home and a lucrative calling to join the Navy. He was suddenly introduced to unfamiliar surroundings, he went through severe bombing and for the rest of his career was faced with the certainty of personal danger. He developed schizophrenia and is now in a mental hospital. Is it possible that these circumstances initiated a mental disorder which in times of peace might have remained hidden and unsuspected?

A.—The present state of our knowledge is very much as described. Even in a clearly hereditary illness such as Huntington's chorea not everyone who has the genetic potentiality develops the disease. In schizophrenia the proportion who do is probably still smaller, studies with uniovular twins indicate that not more than two-thirds of the genetically predisposed become schizophrenic. Environmental factors must therefore play a part. But we have practically no knowledge of their nature, apart from some evidence that head injury may precipitate the illness. The incidence of schizophrenia does not go up in wartime, which would lead one to think that the hardship and stress, which are prolific causes of neurotic breakdown are not the factors which have a causative effect in schizophrenia. In the case described there is certainly a presumption that the radical change in life associated with war service provided a necessary precipitating cause for the illness, and this view would probably be shared by a Ministry of Pensions tribunal. Another point is worth raising. Quite a number of men are invalided from the Services with a diagnosis of schizophrenia which time proves to be incorrect. Men who break down in combat sometimes show clinically a schizo-

phrenic type of picture; and they may still be so regarded at the time of invaliding. Recovery, however, takes places without subsequent deterioration or relapse. The possibility of a mistaken diagnosis should perhaps be kept in mind in the present case.

Vitamin E in Neuromuscular Disorders

Q.—*What are the clinical applications of vitamin E in the treatment of neuromuscular disorders?*

A.—Vitamin E has been widely used in the treatment of neuromuscular disorders—conditions of differing pathology which have in common wasting and weakness of voluntary muscles. These disorders include particularly the motor neurone diseases and the myopathies. In assessing the results of treatment with vitamins it must be remembered that they have all been used in all the incurable diseases, and that both the patient and the observer look for some benefit. It is natural, therefore, that good results should be described, and that these results should be ascribed by some to a specific action of the vitamin upon the causal lesion. So with the distressing progressive diseases of the neuromuscular mechanism, enthusiastic reports have been given of the effects of administration of vitamin E in patients with these diseases. Although the manufacturers of vitamins still quote the enthusiastic papers, these reports have not withstood the test of time; investigations, one of which was carried out by workers of the Medical Research Council, have failed to show any improvement which was not paralleled by other forms of treatment used as controls.

Varicella and Herpes Zoster

Q.—*A person with herpes zoster may infect another with varicellæ, but is the reverse the case?*

A.—Although varicella following contact with herpes zoster is common, the converse is so rare that coincidence may be the explanation of the occasional examples in some people's experience.

Quinine and Impotence

Q.—*What is the justification, if any, of the idea prevalent among civilians and soldiers that quinine causes impotence?*

A.—It is probable that the idea that quinine causes impotence is derived from the use of quinine as a constituent of contraceptive pessaries; quinine salts in sufficient concentration when brought into contact with spermatozoa do kill them. There is no evidence that the administration of quinine reduces the number of motile spermatozoa in the seminal discharge. It should also be remembered, so far as soldiers are concerned, that some soldiers always suspect that any medicine prescribed for regular use is intended to depress sexual desire.

Examining for Drunkenness

Q.—*What are the usual methods of examination in the case of persons said to be drunk in charge of a motor-car? Are blood tests usually done in England? Is the doctor bound to inform the person beforehand that he is examining at the request of the police? What view is a judge likely to take in the event of a doctor's refusing to go to the police station to examine?*

A.—Examinations for drunkenness are dealt with in the standard textbooks of forensic medicine by Glaister, Sydney Smith, and Taylor. Briefly, the examining doctor must direct his mind to the question whether the prisoner was, while he was driving the car, so much under the influence of alcohol as to be unable to control the vehicle properly. The doctor should consider the prisoner's behaviour, speech, gait, breathing, and clothing. Evidence that alcohol has been taken may consist (Glaister) of its smell in the breath, suffusion of the conjunctivæ, flushing of the face, tachycardia, certain abnormal conditions of the tongue, lips and pupils, and tremors. To determine whether the alcohol taken has disturbed normal behaviour the doctor may ask the prisoner the date and time, his address, what he was doing when arrested, and where he is now. He should test the prisoner's vision, co-ordination, and writing. He should be on his guard against neurological disorders, an overdose of insulin, and idiosyncrasy to drugs. All these conditions may be masked by the presence of a small quantity of alcohol.

Blood-alcohol tests are not often done in England, because they need special apparatus and skill which are rarely available. Moreover, their result is not precisely connected with the question of the prisoner's ability to drive a motor-car, though of course a negative finding will dispose of an accusation of drunkenness, and a high positive finding may be conclusive evidence against the prisoner. The urine-alcohol test is just as useful, and has the advantage that urine is easier to obtain. Specimens of either blood or urine should be taken by, or under the direction of, the pathologist who is to make the test. No prisoner is obliged to provide evidence against himself, and examination without consent is technically an assault. The doctor must, therefore, not only inform the prisoner that he proposes to examine him, stating truly the purpose of his examination, but must obtain the prisoner's consent. If the prisoner is unconscious or inaccessible consent to any reasonable examination may be presumed, for his health may be in danger. Blood should not be withdrawn from an unconscious person for test, but if he voids urine this may be tested without his consent. A doctor requested to go to examine a prisoner is not obliged to comply; his action in the matter will not be relevant to subsequent proceedings, and even the fact that he has been asked to go is not likely to come before the court.

Sunbathing in Pulmonary Tuberculosis

Q.—*Why is sunbathing contraindicated in pulmonary tuberculosis? One reason sometimes stated is that sunbathing may, by dilatation of the pulmonary blood vessels, precipitate hæmoptysis, but this cannot be the whole story. Is it the ultra-violet light, the burn, or the rise of body temperature during sunbathing that causes the damage?*

A.—Sunbathing is contraindicated in pulmonary tuberculosis because there is a general belief, founded upon good evidence that extensive exposure of the skin to sunlight produces a focal reaction around tuberculous pulmonary lesions, leading to their extension. It is this activation which causes hæmoptysis, no dilatation of the pulmonary vessels. The causal factor seems to be the action of ultra-violet light on the skin, but the mechanism is unknown. Ultra-violet irradiation of the skin is known to produce chemical changes—e.g., the elaboration of vitamin D—which affect the body as a whole, and the liberation of some chemical substance may be responsible for the unfavourable effect of ultra-violet light in pulmonary tuberculosis. Patients suffering from this disease should expose themselves to the sun as little as possible.

Side-effects of Pituitary Irradiation

Q.—*Is there any literature on x-ray therapy of the pituitary with reference particularly to the untoward side-effects, such as obesity?*

A.—A quick glance at some of the literature rather bears out the implication of this question—namely, that although the theoretical dangers of pituitary irradiation are mentioned by nearly all writers there appear to be few published records of cases where ill effects have been seen. J. B. DeLee and J. R. Greenhill in the 1937 and 1938 *Year Book of Obstetrics and Gynecology* review several articles on x-ray therapy to the pituitary, and mention temporal alopecia and parotitis as recorded complications. C. Mazer and G. Boer (*Amer. J. Obstet. Gynec.*, 1939, 37, 1015) noted temporary amenorrhoea in 1 out of 26 women with regular menstrual cycles treated with low-dosage irradiation, and conclude that the margin of safety is small.

It would appear that most workers who have used x-ray therapy for conditions such as states of menstrual tension, anovular menstruation, and menopausal symptoms have been so impressed with the possible dangers of interfering with various functions of the pituitary (gonadotrophic, thyrotrophic, diabetogenic, etc.) that they have used very small doses, and adverse effects have therefore rarely been seen. This does not mean, however, that rather larger doses—as might be necessary for some cases of menstrual migraine—are also free from side-effects. Thus C. Mazer and S. L. Israel (*Menstrual Disorders and Sterility*, Heinemann), after a large experience of low-dosage irradiation, say that "large doses, such as are employed in the treatment of pituitary adenomas, may produce lasting pituitary deficiency and alopecia. The risk is considerable." The writer

has personal knowledge of three patients treated with moderately large doses, one with diabetes mellitus and two with menstrual migraine thought to be associated with calcification of the roof of the sella turcica. Thereafter two of these patients rapidly gained in weight to the extent of 2 to 3 stones (12.6 to 18.9 kg)

Inheritance of Acquired Characteristics

Q.—Are acquired characteristics ever inherited?

A.—The generally accepted view of biologists to-day is that there is no evidence that acquired characteristics are ever inherited in the straightforward manner presumably implied in the question. For example, parents who live in the Tropics and are heavily sunburned do not have children with darker skins than their cousins whose parents live in England, nor have generations of house training of dogs produced puppies which need no training.

The accepted view is that the genetic mutations responsible for variability occur in a random manner, and the most favourable in any given environment are then selected and so tend to become the most frequent. Many experiments have been done which purport to show a straightforward inheritance of acquired characteristics but so far not one has been satisfactory, or has been impossible to explain on some other basis, as, for example, selection in a population which was not homogeneous at the beginning of the experiment.

To ask, "Are acquired characteristics inherited?" is not to put the question in its most useful form. Since any hereditarily determined character of the offspring must be transmitted in the germ cells of an organism, it is more profitable to ask whether, and if so how, external agencies can affect the germ cells. They will do so only provided they affect the immediate environment of the germ cells by causing some alteration in the metabolism or chemical constitution of the parent. They will do so most easily in organisms whose germ cells are least protected, and whose own constitution is most easily affected by external alterations. Looking at the question from this angle a considerable amount of work has recently been done on yeasts, bacteria, etc. in which there is no clear distinction between soma and germ plasma, and the reproducing cell can be directly acted on by an external agency. It has been found possible, for instance, to accustom *Bacterium lactis aerogenes* to utilize maltose, which it is normally incapable of doing. After a number of generations this acquired ability becomes fixed and inherited. The exact way in which the altered metabolism becomes hereditarily fixed is still unsettled, but if a gene can be reached by an "external" agency and acted upon in such a way as to alter it, there is nothing surprising in the fact that the gene reproduces itself in the altered form. It would be much more surprising if it did not. This direct altering of the chemical processes going on in a reproducing cell by changing its environment is, however, something very different from what is usually implied in the expression "inheritance of acquired characteristics" in higher organisms.

Summing up, an acquired characteristic can be inherited only if it is of such a type as to affect the germ cells directly and in such a way as to alter their constitution in a manner which not only will be reproduced in their subsequent divisions but will also cause the same structural or physiological changes in the resulting offspring as were originally produced in the soma of the parent. Such an event would seem highly improbable in any organism of high complexity, and there is no satisfactory evidence of its ever having occurred.

Infection from Dead Bodies

Q.—The bodies of persons who have died from an infectious disease in a fever hospital may be removed to their homes before burial. Is there any evidence that infective organisms can survive in a body after death and, if so for how long? Has infection ever arisen from the body of a patient who has died from diphtheria? What is the current practice among hospital and health authorities on this question?

A.—The diphtheria bacillus is known to survive outside the living human body—for example, in dust—for as long as 102 days. It has been isolated in the virulent state from secretions of corpses shortly after death, but obviously bodies are not kept without preservation for a sufficient length of time to determine how long the bacillus may survive in this medium.

It may reasonably be assumed that it does so for the short time before burial.

The procedure is governed by Section 163 of the Public Health Act, 1936, which enables the M.O.H. or other registered medical practitioner, by certificate, to prevent the removal of a dead body from a hospital except to a mortuary or a place of burial. The practice no doubt varies, not only from place to place but also locally in different circumstances, depending on such matters as the housing conditions of the family. The tendency is to attach less weight to this procedure as the risk of expulsion of diphtheria bacilli from a properly laid out corpse is slight. The writer knows of no proved instance of transmission of infection from a dead body, but the tracing of channels of infection is so difficult that negative observations of this kind cannot be regarded as conclusive.

Local Penicillin in Gonococcal Urethritis

Q.—In the literature on penicillin I have not seen mention of its local application in gonococcal urethritis. Has any work been done on urethral instillations by means of a small bulb syringe retaining the solution for a time by a light clip or tie penis? Provided retention of the solution could be comfortably borne for a specified period would it not be a more economical method of using penicillin?

A.—We have not come across any published work on the above procedure, but we know (personal communications) that it has been tried. Results have not been very satisfactory, presumably because in the vast majority of cases of gonorrhoea if not in all, the posterior urethra is infected before treatment is begun, and it is neither usual nor wise to attempt to instill a solution of a drug past the compressor urethrae muscle during the acute stage. Simple instillation of a solution of penicillin would be more economical than injection and might prove effective if it were carried out in the very early stages, but even in treating infected wounds surgeons commonly use penicillin parenterally as well as locally. (See also answer to a question published on Jan 19 p 115).

INCOME TAX

Sale of Practice

W. I. sold his practice last October and has had a request from the local inspector of taxes for details of the sale considerations and a copy of the written agreement for sale. He asks whether the inspector has any legal authority for such a request. The practice has been assessed on the basis of "bookings".

* The inspector has no such legal authority, but in those matters he acts as an officer of the Inland Revenue endeavouring to agree the taxpayer's liability before the case goes to the Commissioners who, in the event of an appeal, can call for such evidence as they may require. The request is one which is sometimes made on the ground that the sale price of a practice is to some extent an index of the probable gross earnings. Unless **W. I.** has some reason for declining to give the particulars it may be best to comply with the request, an alternative would be to refuse compliance until the demand is formally endorsed by the Commissioners.

Pay as-you-earn: Employment in Forces

E. R. was a salaried worker before he joined the Forces in January, 1942. As he was in the Forces throughout 1943-4 he received no "forgiveness" of tax for that year, although he had to clear off seven months' arrears of tax while suffering "current" deductions from his pay. Has he any claim to refund?

* The promise of the former Chancellor—to which **E. R.** refers—was that some equitable adjustment should be made where there was an overlapping tax payment and where the tax holiday which the taxpayer was entitled to expect had been lost through the operation of "pay as-you-earn." If **E. R.** becomes an employee when he leaves the Forces (but no if he then becomes assessable under Schedule D) he will apparently come within the promised arrangement. It is understood that particulars can be obtained from the Chief Inspector of Taxes, The Hydro Llandudno, but **E. R.** can do nothing effective in the matter until he leaves the Forces and has subsequently been in employment.

Casual Locumtenency

D. J. while holding a hospital appointment obtained a general practitioner by acting as a locum tenens during a holiday. Is the payment he received liable to income tax?

* Yes. The payment is not liable under Schedule D, but falls within the scope of Schedule E.

LETTERS, NOTES, ETC.

Early Diagnosis of Malignancy

Dr. FRED A. M. LUCAS (London, E.9) writes: Is it possible that there is any member of the profession who feels free to cast a stone concerning the early diagnosis of malignancy? I saw first about four months ago a patient who had a painless swelling in the upper medial quadrant of the breast. No glands were palpable. There was evident mastitis; but there was undoubtedly a hard core to the fairly defined area of mastitis, which had to be considered suspicious. I referred the patient to a particular surgeon (of an excellent voluntary hospital), who concurred regarding the nature of the case and wished to operate. The patient, however, was rather alarmed at the "free hand" naturally required by the surgeon, and asked me for another letter to another hospital recommended by the ubiquitous relative. As this second hospital is also a well-known London (voluntary) hospital, I complied; and the patient attended on about four occasions, seeing both senior and assistant surgeons. Far from satisfied, however, that the belladonna plaster with which they adorned her breast was indeed helping, she returned to me, and I persuaded her to put herself in the hands of the first surgeon and hospital. The breast was removed, but no glands were cleared.

I have just heard, from the department to which she has now been referred for x-ray therapy, that pathological examination of the excised tissues revealed early but definite malignant changes. I humbly suggest that not only the general practitioner need fear the spectre of the "missed" case, and that, while no branch of the profession can or should claim infallibility, it suits us all better to walk warily, and be mindful of the beam in our own eye ere we judge the mote of others.

Miscarriages and Congenital Syphilis

Dr. C. W. F. MCKEAN writes from the Prince of Wales's General Hospital (Tottenham): May I comment on your expert's answer to the question on miscarriages and congenital syphilis (Jan. 12, p. 75). He states that third-generation syphilis is usually regarded as proved possible, if very rare, and that a congenital syphilitic can become reinfected after all evidence of active disease has subsided. I presume the latter must refer to a serological as well as a clinical cure, but it is not clear whether cure by treatment or by Nature is meant. Actually, statistics suggest that a surprisingly large proportion of acquired infections are cured by Nature without any treatment, and this must be regarded as more surely proved than the possibility of third-generation syphilis. The proportion of congenitally infected babies similarly cured would surely be as high, and some infections serious enough to cause congenital stigmata to develop may be so cured. Certainly we have all seen people who we suspected were congenitals but had negative bloods. Therefore, those very rare cases of apparent third-generation syphilis may actually be babies born to mothers who, though themselves congenitals bearing stigmata, were cured by Nature and then reinfected, thus rendering their blood Wassermann-positive again. The extremely high incidence of syphilis certainly renders reinfection easily possible.

Abortion and the Birth Rate

Dr. ANNE M. ANDERSON (Edinburgh) writes: A letter from Dr. B. Dunlop (Feb. 2, p. 192) advocating a relaxed abortion law does not come as a surprise in a largely pagan country such as this, but it calls for comment. Dr. Dunlop's proposal is to have the existing abortion law relaxed so that that section of the community which is producing and bringing up large families may be allowed to kill off its unborn children if and when it so desires. Is it likely that this very section of the community that has been, and is, doing the right thing before God and by the State in bringing up these large families, and which neither knows nor wishes to know birth prevention methods, would accept such an invitation to murder as would be extended to it under a relaxed abortion law even in the name of "liberty"?

Service Conditions and the Ethical Code

"SURG. LIEUT., R.N.V.R.," writes: The letter from "Hippocrates" (Jan. 12, p. 76) is an example and a warning of what can happen under a State system. The indifference displayed to this dental officer's feelings is all too common, and the attitude engendered by the doctrine, so persistently taught in the Services, that one is a medical officer before a doctor. Having seen this in practice most of us believe that this is really detrimental to the Service that preaches it; certainly a fighting man's first duty is to his Service, but he fights better for believing that his M.O. is his friend rather than his superior officer, or his padre his confidant and not the mouthpiece of his C.O. In a recent letter to the *Birmingham Post* Dr. Stanley Barnes writes: "If the doctor is to be paid by the State—in other words, if he is paid indirectly and

not directly by his patient—can anyone with his eyes open believe that the State will not insist upon disclosure not only of diagnosis but also of facts leading up to diagnosis? Whatever promises of official secrecy may be given, there can never be that feeling of security against disclosure which exists where the secrecy of a private doctor is alone at issue." If the new health services are to be a success—and there is no reason why they should not—it is important that their organizers should realize that our first duty is to the sick man or woman not to the local authority, and that we ourselves should reaffirm our discipleship to Hippocrates not to the newer loyalty of the modern State.

Chilblains and Nicotinic Acid

Dr. LEONARD S. CALVERT (Welton, E. Yorks) writes: The interesting letter by Dr. W. Gordon (Feb. 9, p. 218) prompts me to write of yet another condition treated by nicotinic acid with success. A young woman aged 22 had suffered from chilblains of both legs every winter for 6 years, the legs hardly becoming normal in the summer. When first seen she had large bluish, raised, cold, indurated patches the size of a hand extending from the ankle to the knee on both legs. Another woman aged 27 had suffered from chilblains with ulceration on the lower half of both legs every winter for 10 years. Both patients had previously received thyroid, calcium, etc., and, in the second case (? Bazin's disease), gold on several occasions without success. Each patient was given nicotinic acid 100 mg. t.d.s. and vitamin B, 3 mg. t.d.s. A slight transient flushing or pricking sensation of the skin of the whole body, more particularly in the legs, was experienced by both following each dose. In both the chilblains rapidly subsided. The legs assumed a normal contour and warmth. All burning and irritation disappeared. Only a slight bluish discoloration remained. This occurred in three weeks.

Medical Supervision in Boys' Clubs

Mr. IAN M. LESLIE (chairman, London Federation of Boys' Clubs, 222, Blackfriars Road, S.E.1) writes: Recently through your columns (Jan. 12, p. 69) I asked doctors in London if they would be prepared to give a few evening hours, weekly or fortnightly, to "vetting" working boys in clubs affiliated to the London Federation of Boys' Clubs. May I report progress? Twenty-two replies have been received, and as a result nineteen doctors have been or will shortly be placed in direct touch with clubs in convenient districts—to the great benefit of the clubs and their 14-18-year-old members and, I also dare to hope, to the enjoyment of the doctors concerned. Two replies came from consultants who have offered their services to our boys in their particular fields; I have no doubt that club leaders with boys needing special treatment will gratefully make use of this generous offer. There remains one reply for which I have not yet accounted—from a young doctor anxious to help but shortly taking up an appointment in Bristol. He has been placed into touch with the Bristol Federation of Boys' Clubs, who are delighted to have his services, and it has occurred to me, so generous has been the response from London, that there must be many medical men outside the Metropolis who would similarly be glad to help in a boys' club near at hand. There are over 2,000 such clubs affiliated to the National Association of Boys' Clubs in England, Scotland, and Wales, and hardly a city or town that has not got at least one. I am sure that the chairman of the National Association would be glad to place doctors outside London into touch with their nearest club. His address is: The Lord Aberdare, chairman, N.A.B.C., 17, Bedford Square, London, W.C.1. Meanwhile, it only remains for me warmly to thank those who have responded to London's appeal and you, Sir, for setting rolling a ball which I hope will achieve perpetual motion.

First Aid for Cresol Burns

Dr. L. B. BOURNE (London, N.5) writes: In the answer to this question (Feb. 2, p. 191) no mention is made of prevention. A large number of burns come under my notice during the course of the year as a result of splashes from hot zinc chloride, usually caused by a soldering iron being dipped in fluid. We also use hydrofluoric acid in quantity, and this is likely to cause burns if preventive measures are not used. A good barrier cream will reduce considerably the risks not only from hot cresol but from most industrial skin hazards. It must be emphasized that a specific barrier cream against cresol should be used. There are a number of creams being offered by the makers to protect against "all risks." These should not be used under any circumstances.

Disclaimer

Dr. C. B. MOLONY, resident medical superintendent, Waterford Mental Hospital, writes: My attention has been drawn to a sensationally headed and luridly worded article on schizophrenia which appeared in an English Sunday newspaper on Feb. 24, and in which my name and address have been quoted. I wish to dissociate myself from the article in question, and have written a letter of protest against its publication in the form in which it appeared to the editor of the paper.

LONDON SATURDAY MARCH 23 1946

THE HEALTH PROBLEM IN BERLIN

(JULY, 1945, TO JANUARY, 1946)

BY

P. G. HORSBÜRGH, G.M., M.R.C.S., L.R.C.P., D.P.H.

AND

H. A. RAEBURN, M.D., F.R.C.P.Ed., D.P.H.

(Public Health Section, Military Government British Troops Berlin)

As a political experiment in international co-operation the government of a city such as Berlin by four Allied Powers—with different outlooks and different aims—is unique. The importance of the success of such an experiment is widely realized, and it was thought that an account of the problems facing and the work done by the Public Health Section of the British Military Government would not be without interest. These problems will be described as they presented themselves to the Public Health Section. The situation was chaotic on arrival—in spite of the existence of a German administration, normally very efficient, struggling to resuscitate itself. It must be appreciated that it was always very difficult to obtain information as to exactly what was occurring, but anyone who saw the city last July and sees it to-day cannot but be struck by the general improvement of the health conditions.

General Situation

The story of Berlin during the year 1945 is well known. Until the Russian advance early in the year the city's Health Department had, in spite of the heavy bombing, managed to keep the health services functioning. In the early months of the year the city became more or less an operational area and disintegration started, culminating in complete chaos with the battle for Berlin and the city's capture on May 2. There then followed a period of Russian occupation, when military and political considerations were paramount and the health of the population was of secondary interest. The British troops arrived on July 4, and British military government began to function on July 12.

Berlin, a city with a pre-war population of 4,306,500, is governed by a "Magistrat," which includes a Health Department headed by a Medical Officer of Health. The city is subdivided into 20 districts, or Bezirke, each with its municipal authority and health department. Unlike the Metropolitan Boroughs of London, the Bezirk is not an independent authority, but comes completely under the control of the city's Magistrat.

The actual German administration was left unchanged by the Allied Powers, but each Power became responsible for a section of the city*—comprising a number of Bezirke, as shown on the accompanying map (see p. 425).

Control over the German Magistrat is exercised by a joint Allied body known as the Kommandatura. Policy is determined at meetings attended by the Commandants (the general officers commanding the four Allied contingents in Berlin). Technical matters are dealt with by committees of the Kommandatura, comprising a representative of each Allied Power. Meetings are held weekly, or oftener if necessary, when problems are discussed, and if agreement is reached appropriate instructions are sent—in the case of the Commandants' meeting, to the Magistrat of the city, or, on technical matters, by the committee concerned to the appropriate department. The four Allied Powers provide a chairman for the main meeting and committee meetings in rotation, each chairman holding office

for one month. The Allied Power providing the chairman is responsible for the secretarial work of the Kommandatura.

The experiences of the different committees vary, but the Public Health Committee was generally successful in agreeing on all measures to be adopted. In such a committee the language difficulty is a real one and agreements have to be couched in general terms, a certain latitude in interpretation is inevitable.

Like any other great city Berlin is not self-sufficient and obtains supplies from all parts of the country. Of particular importance from the health point of view is the food supply, which in normal times largely comes from the rural country surrounding the city. It is a cardinal principle that the four Allied Powers accept responsibility for feeding the population in their own sector. As Berlin is situated in the Russian zone the normal larder of the city is not available for the British United States, and French authorities. The communications, with their respective zones for road transport, are along the autobahn from Berlin to the west. The nearest point in the British zone is Helmstedt, some 100 miles from Berlin and transport is limited to this road. Military traffic is unrestricted, but German civilian traffic requires a Russian clearance before it can pass over the border. Rail transport from the west is now running, but there is only a single-track line functioning on the 80 miles between Berlin and the Elbe at Magdeburg. This line is under Russian control and the fact that it is a single and not a double track reduces its carrying capacity some twenty times.

The above sketch of the conditions in Berlin is intended to give an idea of the background against which public health problems must be judged. It is now proposed to describe some of the main health problems encountered.

Staffing of Health Departments

It is well known that the Nazi party permeated the public services in Germany. The Allies all agree on the necessity for denazification but the policies of the different Powers vary somewhat. The Russian policy insists on complete elimination of any party member. British policy recognizes that party membership may have been merely nominal, and allows such persons, after "screening" by Special Branch officers, to be retained in and appointed to office. (In certain categories—e.g., SS—removal is mandatory.)

The Russian policy was applied for two months before the British occupation. The medical officer of health of the city was an extremely capable man, of the Bezirke's, one medical officer of health was an old but very experienced man, two were inexperienced and had got their position more on political than on professional grounds, and the fourth was "hopeless."

The medical officer of health described as "hopeless" fully justified the description, and attempts were made to find a substitute. The city medical officer of health recommended a suitable medical officer who had, unfortunately, become a nominal member of the Nazi party. This doctor was "screened" by Special Branch officers, and no objection to his appointment was made. He has proved himself a most capable official in spite of a campaign of anonymous letters and

* The French took over their sector on Aug. 12, 1945. Previously this sector came under British administration.

posters on walls abusing both the British Military Government and himself.

Other similar difficulties arose. For instance, the Director—viz., the lay superintendent—of one hospital was found to be ignorant of the number of beds in his hospital—his only experience of the job being a short period in the hospital office as a clerk some years ago.

"Nazi-ism in reverse" constituted another problem. The fact that the Nazi system was one of the most abhorrent institutions known to mankind did not, in itself, make those who fell foul of it into saints! A large number of the finest Germans suffered from this system, but unfortunately some of the less reputable victims (or self-appointed victims) obtained positions of influence and started victimization of their rivals. This victimization took the form of dismissing persons from their positions on the grounds that they "belonged to the party." To prevent this victimization the British Military Government reserved to itself the power of dismissal. Cases frequently came to light involving such persons as hospital nurses who, when "screened" by Special Branch officers, were found to have been mere nominal members of the party, and in some cases had been forced into it.

This problem is stressed, as much criticism of British Military Government policy in connexion with de-nazification has arisen. The problem is a difficult one—especially for a technical service, such as public health, where replacements are not easily made; its solution is not simply deciding between black and white.

General Sanitation

In normal times Berlin had an extremely well organized system of water supply, sewage disposal, and refuse disposal. On the arrival of British Military Government the organization was chaotic and much of the equipment and installations had been damaged. The city obtains some 90% of its water from shallow wells and the remaining 10% from surface water. There are normally 87 interconnected pumping stations. No gravity reservoirs exist, the maintenance of pressure depending on the functioning of the pumps. It was estimated that in the city there were 3,111 known major breaks to the mains as a result of the bombing and fighting. The waste of water was enormous. In July the estimated measured consumption was 50 gallons per head, but the bulk of this water was running to waste. The pumping machinery worked intermittently, causing frequent negative pressure.

The sewage organization of Berlin consisted of three systems leading to sewage farms and sewage plants. There had been 2,323 known major breaks, and only some 20% of the sewage reached the disposal works. The rest seeped away into the sandy soil, but did not cause as much nuisance as might be expected. Its presence was, however, very obvious in the city's many waterways and canals.

The above description will make clear the danger of water contamination. The only radical cure was the complete repair of the water and sewage systems, and such work was given the highest priority by the Public Works Department. By January 106 major defects to the water system and 399 sewage defects remained to be repaired. As a stop-gap measure the water was chlorinated. It was necessary to get quadripartite agreement to such a measure; this caused some delay in its inception. The water was examined by the "Reich Institute for Water- and Air-Hygiene" for signs of contamination, and by a British Army hygiene section for the presence of residual chlorine. Results were also checked by a British mobile laboratory, and were more or less consistently satisfactory after heavy chlorination. All water for British troops was specially chlorinated in military water-carts, etc. As an additional precaution the population was advised to boil the water—rather a counsel of perfection when it is remembered that very few people had even enough fuel for cooking. That these methods were effective is shown by the fact that, so far as is known, the typhoid epidemic which raged from August to November was not water-borne.

On our arrival the refuse-disposal system was more or less non-existent—the main trouble was that of transport. The Germans largely used a very cumbersome refuse-wagon requiring two heavy horses to move it; the only horses available were underfed light-draught animals. Much of the refuse was normally

taken outside the city by barges, but the waterways were blocked through war damage. At first refuse was disposed of by burial in gardens and open spaces. Where this was not possible refuse-carts were left at suitable points of the street and moved when filled to overflowing. It was necessary to clear the waterways before an adequately organized system could be instituted.

Casual fouling caused a certain amount of difficulty, which was not surprising, as few public lavatories were functioning and thousands of German refugees were thronging the city: a city of ruined buildings gives extensive opportunities for such habits! Energetic measures were taken to supply public lavatories, whose provision overcame this nuisance.

Nutrition and Fuel

The feeding of such a city as Berlin is an immense problem, and the difficulties, due largely to the transport situation and the cutting off of normal sources of supply, have already been briefly indicated. The conditions on arrival were bad. The casual observer going about the streets could not fail to note the high proportion of pale anaemic faces, and the extremely slow rate at which gangs of labourers, etc., did their work. As an illustration of this, some British medical stores supplied for the use of Berlin had to be unloaded, and it was estimated that 18 labourers were required. In actual fact 50 had to be pressed into service to get the work completed in the allotted time. The medical observer would have noticed other signs. The time spent by patients in hospitals was above the average. Dysentery had a case mortality of 28%. Cases of hunger oedema could be seen in almost any hospital.

The rationing system in force divides the inhabitants into five broad classes:

	July, 1945	Jan., 1946
Class I: Heavy workers ..	2,443 cals.	2,443 cals.
Class II: Workers ..	1,957 "	1,957 "
Class III: Sedentary workers ..	1,581 "	1,581 "
Class IV: Children up to 15 yrs.	1,500 "	1,500 "
Class IVa: " 6-9 yrs.	—	1,375 "
Class IVb: " 6-9 yrs.	—	1,473 "
Class IVc: " 9-14 "	—	1,543 "
Class V: Non-workers ..	1,200 "	1,504 "

* Milk ration: Children up to 1 yr., $\frac{1}{2}$ litre per day.

" 1 " 6 yrs., $\frac{1}{2}$ " "

" 6 " 9 " $\frac{1}{2}$ " "

Mothers: 2 months before and 4 months after birth, $\frac{1}{2}$ litre per day.

Hospital patients: $\frac{1}{2}$ litre per day.

It must be remembered that, apart from the black market, Berliners had little opportunity of supplementing their rations. During the autumn many Berlin families spent the week-end walking into the surrounding country and trying to buy extra food from farmers—who, in the Soviet occupation zone, must hand over 75% of their produce to the authorities, but are permitted to dispose of the other 25% as they wish. The more enterprising Germans certainly obtained some food in this way—mainly vegetables. Most of the food was obtained by barter and was liable to looting on the way back to Berlin. In addition to this innocuous type of black market, food could be obtained on the real black market, but at an exorbitant price. One doctor used most of her salary for two months to give her parents a present of a kilogramme of butter—at the cost of 800 RM.=£20 nominal value.

The Class V ration was, with grim humour, known by the Germans as the "death class" and did mean slow starvation. It is true that in actual fact comparatively few people had to subsist on this ration alone—the majority of families having someone on a higher scale. The housewife received a Class V ration card in spite of the fact that she had a most strenuous job in catering for her family. This important class of citizen always seems to get "more kicks than ha'pence."

The effect of a diet of 1,200 calories alone was well illustrated in one of the prisons. Even prisoners sentenced to hard labour received this diet and could obtain no supplement. Many had to be kept in bed as they were too weak to work. Some deaths occurred from malnutrition alone. There were many cases of hunger oedema. When oedema developed, the prognosis was bad and death usually occurred within 14 days, as it was quite impossible to provide the correct treatment. An improvement has now been made, and working prisoners receive Class III ration.

In the early days of the British occupation (July to August) it frequently happened that the ration cards were not honoured.

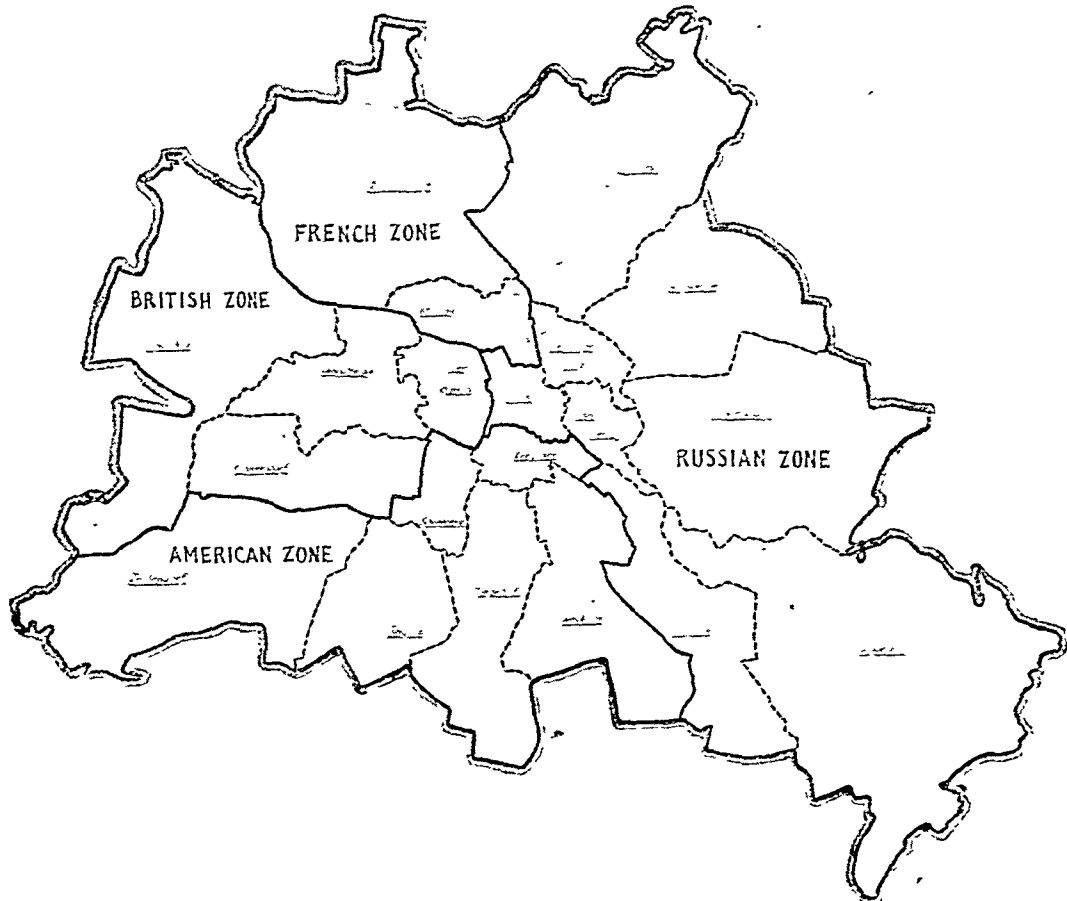

the scanty ration of fats being as much as two months in arrears. The nutritional condition of the population gave rise to much anxiety—especially with the knowledge that a winter had to be faced. Fortunately the mechanism of rationing was greatly improved by the Food Section of Military Government. By November the ration cards were being honoured and many improvements were made, which will be seen in the foregoing table. After 6 months of occupation the nutritional state of the people was much improved, and, while the winter is not yet over at the time of writing, it appears that serious epidemic disease may be avoided.

The protective foods—fats, milk, etc.—were extremely scarce, but in the early days the difficulty of the food situation was such that never once was the Public Health Section asked to advise

and distribution of the rations are so irregular that even such basic foods as bread and potatoes are bought for the week and eaten up in a few days, after which time the dietary intake is extremely low until the next ration becomes available, not necessarily at the beginning of the next ration period. This impression is substantiated by values from one-day diet histories, which give figures ranging from 1,830 calories to 384 calories from rationed foods alone on a basic ration of 1,163 calories."

Fuel was also extremely short in Berlin. Supplies had to be brought from the Ruhr, and from Silesia in the Russian zone. In addition to being scarce, much coal was of the soft brown variety which was not suitable for many of the furnaces in use in the city.

Public utilities had the first call on fuel, after which hospitals had a high priority. Distribution was irregular at first; large

on what foodstuffs should be brought into Berlin. This was not due to any lack of interest in the medical side of the problem—it meant that any food possible was obtained. In such circumstances nutrition experts will perhaps think leniently of the Public Health Section when it is stated that vitamins were not a priority demand! By November the question could be considered, and the same policy of "get what one could" was adopted. Cod-liver oil and vitamin tablets were sent in from the British zone and distributed to children.

The above description of the food situation is based purely on observation and knowledge of the administrative machine. Berlin was visited by a British nutritional team in September, 1945, and the following is an extract from their report:

"Dietary information covering the previous week has been collected on 65 households (176 people) and dietary intakes of a single day's meals have been recorded for approximately 80 of these people. Few of these daily records equal the rationed amount the people alleged they were able to buy. There is no peak period of consumption as in Dusseldorf. The impression is that the availability

of hospitals were often running with only the most meagre reserves and had to curtail their work as no steam was available for sterilizing. The Economic Section of Military Government appreciated the importance of hospital needs, and by November a sufficient if not a liberal amount was available. Economies, such as not heating corridors, had to be exercised, but during the winter no hospital had to close down on account of lack of fuel.

The supplies available allowed no coal for domestic purposes, and the gas and electricity supplies were strictly rationed. Use was made of the extensive wood in the forests which surrounded Berlin. The population shivered, but, by the use of wood fuel and by whole families occupying one room only, deaths from exposure were prevented. The lack of fuel was probably one of the factors in the high death rate from respiratory disease among old people and infants. One result was a high incidence of skin disease in young children due to the lack of washing facilities.

Dysentery

When the British took over their sector in July they found a dysentery epidemic in progress. The reason was not far to seek: disorganized sanitary services, lack of personnel to advise on precautions, and flies breeding in the hot weather. The extent of the epidemic is shown by the following statistics:

	British Sector		Total for Berlin	
	Cases	Deaths	Cases	Deaths
July, 1945	1,203	62	4,332	906
Aug., "	985	170	3,398	1,014
Sept., "	279	57	1,764	608
Oct., "	217	84	923	268
Nov., "	256	57	1,029	215
Dec., "	233	77	871	276
Jan., 1946	55	11	306	51

The preventive measures adopted consisted in the reconstitution of the normal sanitary services. The improved conditions began to make themselves felt by August, but it was perhaps fortunate that this month was exceptionally cool.

The disease was mainly of the Flexner type. Of great interest is the high case fatality—28% of all cases from July to November. This high mortality can be explained by the poor nutritional state of the population. Visits to hospitals indicated that many of the fatal cases, although infected with the dysentery bacillus, were in fact cases of debility and malnutrition.

It must be remembered that treatment facilities were also lacking. No sulphonamide drugs were available, and the food supplies—black bread, etc.—did not allow proper dietetic treatment. Necropsies on many cases showed a large intestine with no inflammatory reaction, in spite of the fact that the Flexner bacillus had been demonstrated.

Typhoid Fevers

The extent of the typhoid epidemic in Berlin is shown by the fact that 12,740 cases occurred in the city (2,397 in the British sector) from July 12, 1945, to Jan. 12, 1946. It was known that many cases were occurring in July and August, and all doctors, nurses, and others likely to come into contact with the disease were protected by inoculation. About the middle of August, however, the number of cases suddenly increased, coincident with an increase of refugees, and it was felt that some more drastic measures should be taken.

Typhoid differs from dysentery by its long incubation period. It was estimated that some 80% of the cases were imported and were occurring among refugees arriving in the city from the east. The health conditions and standard of hygiene of these people were poor, and many cases resulted from direct contact. In view of the fact that between 700 and 800 cases were occurring each week, careful epidemiology was out of the question, and "shot-gun" methods had to be adopted. Compulsory immunization was decided upon, and an order was issued to this effect on Aug. 24—the other Allied sectors adopting the same procedure. It is interesting to note that such a, to us, revolutionary order was accepted by the German health authorities more or less as a matter of course. Stations were soon set up in the districts, and ration cards afforded an easy method of checking those who had been treated. Some delay was experienced in collecting supplies of vaccine and syringes, and inoculation started early in September. In the British sector over 90% of the population had been treated by the end of October.

Statistics of typhoid cases are given below:

	British Sector		Total for Berlin	
	Cases	Deaths	Cases	Deaths
July, 1945	79	—	245	22
Aug., "	444	27	1,688	177
Sept., "	688	53	3,922	406
Oct., "	508	65	3,059	336
Nov., "	354	61	1,979	328
Dec., "	240	47	1,452	256
Jan., 1946	84	17	395	75

Clinically the disease showed no special feature. The proportion of each type is not known, as bacteriological facilities were limited; the bulk of the cases were true typhoid. The

case fatality was approximately 12%. The explanation of this more or less normal fatality rate is probably that the poor diet did not have such a bad effect on a disease for which a low diet is part of the treatment. Hospital accommodation was fully taxed and many patients had to be treated in their own homes.

The inoculation of the Berlin population against the enteric group was carried out in the presence of an epidemic, and there was evidence that the "negative" phase made people more susceptible. Doctors were continually reporting the occurrence of the disease in inoculated persons, with a considerable number of severe and fatal cases. One physician thought that the disease was just as severe in inoculated persons but that complications were less frequent.

At this stage it has not been possible to analyse results and assess the efficacy of inoculation in the presence of an epidemic. The point to be remembered is that it is likely that in the spring of 1946 large numbers of refugees will be passing through the city and inoculation ought then to prove its value.

Typhus

The advances made in the control of epidemic disease cannot be better illustrated than by Berlin's experience of typhus since July, 1945. Apart from the fortunate fact that it was summer-time, British Military Government found a stage that seemed to be set for a large-scale epidemic. The chaotic and semi-famine conditions have already been described. In addition there was an extensive movement of population from the eastern districts, where typhus was known to be prevalent, into a community which had no immunity against the disease.

A few cases were reported in other sectors of the city towards the end of July. It was known that the refugees who arrived were lousy, and arrangements were immediately made for their delousing: nothing could be done with those who "filtered" in to relations. Fortunately the Berlin population has a high standard of hygiene. Effective delousing was made possible only by the use of D.D.T. and the provision of necessary dusting equipment—from Army sources. R.A.M.C. sanitary officers and N.C.O.s soon taught the German health department staff the necessary technique and supervised the work. Without D.D.T. dusting, louse control would have been almost impossible, as most disinfection stations were damaged and fuel was difficult to obtain.

There was not enough typhus vaccine to carry out a wide-spread inoculation campaign, but this protection was given to doctors, nurses, refugee workers, and others likely to come in contact with cases. This was completed by the end of September.

A number of cases occurred in the other sectors, but the British sector remained free until the end of October, when some 10 cases or suspected cases occurred among refugees. Since then a few cases have been occurring every week, but there has been no epidemic outbreak. All cases in the British sector, with two exceptions, were infected before arrival. The eastern part of the city had the largest number of cases, partly because west-bound refugees arrived in this sector, and partly because the conditions of overcrowding were worse owing to more extensive damage.

The following statistics cover the first 6 months (July 12, 1945, to Jan. 12, 1946) of British occupation:

	British Sector		Total for Berlin	
	Cases	Deaths	Cases	Deaths
July	1	—	1	—
Aug.	1	—	18	7
Sept.	2	1	26	7
Oct.	2	—	27	4
Nov.	4	2	25	21
Dec.	20	6	126	14
Jan.	7	3	61	—

Clinically the disease was moderately severe, with an 11% case fatality. Typical exanthemata were only rarely seen, and perhaps the most striking symptom was the "typhoid" state and delirium—a fantasy of one German P.O.W. returning from Russia being that he was the Tsar. The Weil-Felix test was used throughout for diagnostic purposes. Convalescence was slow—not surprising in debilitated patients.

One German physician who had much experience of typhus gave it as his opinion that the disease had not become more widespread because lack of fuel caused all German households to be cold and the low temperature discouraged the louse from miterating. Be that as it may, the occurrence of typhus was more or less inevitable in Berlin. The limitation to sporadic cases rather than an epidemic is a great tribute to modern preventive methods—especially as, while exact information is not available, reports indicated that the disease reached epidemic proportions in certain other cities in Eastern Germany.

Veneral Disease

Many lurid articles have appeared in the lay press with regard to prostitution and venereal disease in Berlin, and it cannot be denied that the position was bad. The Germans had experienced a rise in incidence on account of war conditions, as had occurred in Great Britain. As already noted, the health services had been completely disorganized, Berlin had been the scene of much fighting and after its capture the inevitable licence and promiscuity took place. Families had been separated, and many women had no news of their menfolk for months. Food was desperately short, and many were no doubt driven to prostitution to obtain extra nourishment.

It is very difficult to obtain accurate figures of the incidence. A survey in one district disclosed the fact that 10% of the total female population were infected with venereal disease. It is likely the incidence was even higher, and has been put at 40% of the total female population.

The problem resolved itself into the tracing of infected females and ensuring they were treated. A "Vice Squad" of British military police was formed to work with the German civil police in tracing the contacts of Service cases. At first the proportion traced was small, but after the system was properly organized about 80 to 90% of contacts were traced. These persons were, if infected, retained in a special hospital till rendered free from infection.

A variant of this method was the organization of raids on "black spots"—e.g., notorious cafés where much "picking up" took place. The war has not altered completely the habits of a city, and many of the "black spots" were well known to the German criminal police. Other "black spots" developed owing to the presence of Allied troops. When a raid took place all women who could not produce a suitable identity card or were "known to the police" were apprehended and medically examined by the German health authorities. It is probable that many "amateurs" have been missed by this method, but the results of some raids are interesting.

	No. of Women Sent to P.H. Dept. for Examination	No. of Cases of Syphilis	No. of Cases of Gonorrhoea
Sept. 1945	247	10	60
Oct.	52	—	3
Nov.	52	1	2
Dec.	27	10	53
Jan. 1946	238	14	71

The raids did not seem to cause much resentment among the German population. Except for a few instances, all were carried out with almost excessive politeness on the part of everyone concerned. No doubt the presence of British military police had a deterrent effect on any male partner who was inclined to be truculent. After a number of raids had been made in a particular district the proportion of women found infected decreased.

Such raids might not be tolerated in normal times but, in the peculiar situation of Berlin in the autumn of 1945, it is considered the results justified this procedure.

Another factor in encouraging the spread of the disease was the inadequacy of treatment facilities. In Berlin the system of public V.D. clinics has not been developed as in Great Britain, and most of the treatment is in the hands of specialist doctors, who see patients in their own consulting rooms. Such doctors were short of sulphonamides. British stocks were brought into Berlin, but it was impossible to supply such drugs to doctors working privately, as there was a flourishing black market in this commodity. A compromise was effected by issuing drugs to the health departments and insisting that they supplied drugs only to recognized hospitals and centres set

up for the purpose. The illicit treatment of venereal disease by black-market drugs undoubtedly caused the development of many sulphonamide resistant cases.

Refugees

The end of hostilities brought with it the necessity for returning millions of people to their homes. Allied nationals—"displaced persons"—were given priority over Germans, and in the British zone their care absorbed most of the energy of the Military Government detachments. In Berlin "displaced persons" never constituted a problem, as they were few in number, but the German refugee question very soon began to cause much worry. Food was short and additional mouths to feed threw a great strain on the available food supplies.

Attempts were made to prevent refugees coming to Berlin at all unless they were bona fide residents of the city. In theory their entry was forbidden, but in actual practice they came in large numbers. Early November was probably the peak period, and it was estimated that they were reaching the city at the rate of 20,000 a day, of whom some 2,000 remained in the city. As a matter of interest, the population increased from 2,947,500 in August to 3,038,777 in December, a considerable number never registered.

The problem was one of refugees from the east. This point is stressed, as the British authorities had no control over and very little information concerning the source of refugees—the ceded territories—or their entrance into the eastern part of the city. Refugees arrived in the city by train and on foot. The conditions of rail travel were beyond description. An everyday sight was famulus groups, usually without any menfolk, trudging through the streets carrying their belongings on their back or, if lucky, on hand-carts. Accounts have appeared in the lay press about the terrible conditions of these people; these reports, although somewhat sensational, gave essentially a true description.

In some of the refugee camps that, as described later, were set up it was possible to see sights which showed only too well the aftermath of war. Sick bays were provided, and they were largely occupied by moribund cases which hospitals would not accept. One curious sign was the unemotional way in which a mother with perhaps four children would state that she had heard nothing of her husband for months or even years. Many seemed to have lost all normal human emotions.

When the stream of refugees began in August it was imperative that something should be done and refugee camps were set up in the British sector under the supervision of the Displaced Persons Section of Military Government, which was responsible for dealing with the refugees. These camps were run by the Germans themselves—much credit going to a number of German Red Cross workers. Conditions in the camps were not good but they did provide the minimum of care and, what was more important, prevented large numbers of potential disease-carriers from becoming lost in the city. Typhus was an ever present danger and the concentration of refugees in camps allowed effective delousing with DDT powder.

With the co-operation of the authorities of the British zone, many refugees were evacuated to the west in October. Towards the end of this month and early in November the numbers increased alarmingly. One camp for 1,500 at one time housed almost 8,000 people and it was essential to make definite arrangements for dealing with them. It would have been preferable, from the point of view of the city, to prevent the arrival of refugees altogether but such a course was impracticable, and it was necessary to set up camps where refugees could be under control. By January, 1946, accommodation for some 10,000 had been provided. In addition a more or less regular evacuation of refugees to the west was arranged, trains running when the occasion demanded it. By December and January the numbers reaching Berlin had declined and the accommodation provided was not taxed.

The main problems were accommodation and feeding. Accommodation in a heavily damaged city like Berlin was not easy to find, but use was made of barracks, etc. Until enough camps were set up, large numbers disappeared "underground" and lived in cellars and rooms in bombed buildings. Many appeared from nowhere when there was any chance of evacuation to the west. Refugees were not given ration cards, but

were fed from soup kitchens at the camps. In the estimated requirements of the city the Food Section had a 10% reserve which was available for such needs.

From the medical point of view the refugees caused many problems. They brought with them much disease—some 80% of the typhoid and almost all the typhus cases. Many suffered from debility and took up much hospital accommodation. The minor-treatment rooms and sick-bays in the camps required medical supplies at a time when the shortage was acute. Lacerated feet in undernourished people were particularly difficult to treat.

Another problem was the returning prisoners of war passing through Berlin. The responsibility for such men belonged to British Troops Berlin, and a transit camp was set up on the outskirts of the city. The Public Health Section arranged for a near-by civil hospital to admit any needing hospital treatment. Many had infected wounds necessitating a long stay in hospital. Anyone wishing to see to what a condition the once proud Wehrmacht, in ragged uniform, had fallen had only to visit this camp. It would discourage the most belligerent from wishing to take the risk of starting a war.

The subject of refugees has been described fully, even though the responsibility was not merely a medical one. It showed the aftermath of war at its worst. Many more refugees are still to be moved, but it is to be hoped that the agreement to move people in a more humane and orderly fashion will be carried out, as the terrible conditions of the autumn of 1945 must lead to bitterness.

Good work was done by both Allied and German authorities and voluntary societies in the relief of suffering, under difficult conditions. On the British side, mention will be made only of the fine work of the Friends Ambulance Unit stationed in Berlin, and the way in which the ordinary British soldier gave help to refugees with whom he came in contact—far beyond what mere duty demanded.

Personal Health Services

The first stage in the development of the modern health service dealt with problems of environmental hygiene and the control of infectious disease; the conception of personal health services was a later development. It is curious to note that in the rescue of the Berlin health services from the chaos into which war had thrown them the same sequence was followed, and only after some three months of occupation was it possible to give much attention to the personal health services.

As might be expected, tuberculosis has greatly increased. The environmental conditions—poor food, bad housing, etc.—encouraged its spread, and the lack of hospital beds prevented the isolation of cases. Like any modern city, Berlin owned many sanatoria outside its boundary, and such beds were now largely unavailable. Transport difficulties prevented use being made of institutions in the British, French, and American zones of occupation. A large tuberculosis hospital centre just outside the boundary of the city in the Russian zone was in use by the Red Army for military purposes.

The fact that very little could be done had to be accepted. It is true that a general improvement of living conditions and food supply was taking place, but no immediate steps could be taken. As many hospital beds as possible were made available for tuberculous cases. Persons who could produce evidence that accommodation in a sanatorium was available for them in some other part of Germany were granted travel permits, but there was always the feeling that the signing of such a recommendation merely absolved one of the responsibility of doing nothing. Undoubtedly some got safely to sanatoria, but it is certain many suffered from the rigours of the journey.

The following statistics for the city of Berlin are of interest:

1938: Incidence of tuberculosis per 10,000 per annum = 25.8
July 12, 1945, to Jan. 12, 1946: Incidence of tuberculosis per 10,000 per annum = 48.9

Maternity and child welfare clinics caused no special difficulties. It so happened that the premises in which such clinics were held had not been so badly damaged as to make them unusable, and the German health authorities soon got them working again. They were largely staffed by women doctors, which meant that there were no special staffing difficulties. The functions of the clinics are the same as in Great Britain.

The Germans seem to use these clinics freely, and it is claimed that all children are either seen by health visitors or attend the clinics at least once. Some 70% of children under 1 months attend regularly. The work of the clinics was handicapped by the lack of medical supplies and supplementary nourishment. They served, however, a particularly useful function in instructing mothers how to make the best use of the child's ration.

In the British sector of Berlin there was no actual shortage of general practitioners, but they worked under considerable difficulties. Hardly any had motor-cars—even a medical officer of health 68 years old in a semi-rural district did most of his visits on a bicycle—and only a few had a telephone. Conditions are gradually improving, and doctors now receive priority in the provision of telephones, motor-cars, etc. Many minor difficulties over accommodation arose, but it was agreed that a doctor's house should not be requisitioned by the military, and arrangements were made for a special issue of fuel for heating surgeries.

Many specialists had been evacuated from their hospitals and others were prisoners of war. The hospitals soon tried to collect their staff again, and when anyone was specially required application was made to the Control Commission for this particular person. A considerable number of medical men thus returned to Berlin at a comparatively early date.

Hospitals

Hospitals, like other buildings, suffered from the effects of bombing and the battle for Berlin. While comparatively few hospitals or hospital blocks were completely destroyed by direct hits, all in the British sector had been damaged to a greater or lesser degree. A number of institutions outside the city were no more available for Berlin's population. The pressure on the hospital beds was great. In July there was a dysentery epidemic—shortly to be followed by a typhoid epidemic. The city was full of refugees with no homes who, if ill at all, had to be admitted to hospital; there were many wounded requiring treatment. There was another cause for the strain on the bed accommodation. Owing to the poor nutritional state of the population and the lack of drugs and supplies, many patients had to be kept in hospital longer than usual.

The first step was to arrange for the repair of the hospitals, as in August it was estimated that 60% of the beds would be put out of commission in bad weather. It was agreed by all sections who had a call on labour and materials that hospital repair must have a high priority. There are in the British sector of Berlin a few large municipal and voluntary hospitals of over 500 beds, a considerable number of medium-sized hospitals of 100 to 500 beds, and many small hospitals of 50 to 100 beds. Many of the small hospitals are what in Great Britain would be looked upon as nursing homes. In September the Health Branch of the Control Commission initiated for the British zone of Germany and the British sector of Berlin a Winter Plan which, so far as Berlin was concerned, meant the finding of 2,000 more beds in the British sector. In a badly damaged city, buildings for 2,000 beds were not easy to find, but it was done. Equipment was the difficulty, but simple if not lavish equipment was sent up under British auspices from the British zone. This was immediately issued to these reserve hospitals.

The following statistics give the hospital position in July, 1945, to January, 1946. They refer to the British sector only:

	July, 1945	Jan., 1946
No. of hospitals over 500 beds	3	5
" " from 200 to 500 beds	5	9
" " under 200 beds	29	30
Total No. of hospitals in section	37	44

No. of beds available: July, 1945—5,817; Jan., 1946—9,143

By January, 1946, the position was such that, in the absence of epidemics, the hospital provision could be considered satisfactory.

† Sepsis in wounds was one of the commonest causes of long stay in hospital. Many German prisoners of war arrived on their way to West Germany in a terrible state—septic amputation stumps were frequently seen. The German hospital is normally a well-run institution, but one of the most noticeable features in wards being used for prisoners of war was the all-pervading stench of pus. It made one imagine one had returned to the pre-Listerian era.

Medical Supplies

In July there was an acute shortage of drugs and other medical supplies. The position was such that numerous hospitals had to curtail or stop their surgical work on account of deficiency of anaesthetics. Sulphonamides were practically unobtainable in hospitals and chemist shops were empty. The repercussions on a population suffering among other things, from a dysentery epidemic need not be stressed.

The matter was so urgent that it was decided to take steps to relieve the position in the British sector. Early in August some 60 tons of mixed medical stores were received from British sources, and a British medical store was set up. On account of the extensive black market—one ampoule of penicillin would fetch the equivalent of £75—the drugs were issued to hospitals only. The system worked well, and by December some 500 tons had been brought in from British sources.

At the early meetings of the Kommandatura an attempt was made to develop a uniform drug supply policy for the city of Berlin as a whole. The idea was that the Magistrat would inform the Kommandatura of what drugs were short, and demands would be made to the four Allies who would so far as possible, agree on what each would supply for the city as a whole. It, however, was more or less impossible to get enough information from the city authorities. The British view was that an urgent need existed which could not wait until the actual or potential German stocks could be accurately determined. Complete agreement could not be reached on this point by all four Powers and therefore the need of the British sector was met from British sources, other Powers dealing with their sectors in their own way. By December the hospitals in the British sector, to which issues were first limited, had an adequate if not liberal supply of drugs and it was then possible to agree to the dispensing of out-patient prescriptions normally obtained from chemists.

The German pharmaceutical industry is a powerful one, and a number of big firms have factories in Berlin. They may soon begin to try to re-establish their production, and if the firms are regarded by the medical officer of health of Berlin as producing reputable and essential drugs the British Military Government might give such manufacturers assistance to obtain raw materials and finished products from outside the city.

Considerable stocks should soon be obtainable through normal trade channels, but it is claimed that the action of the British authorities in making drugs available during the period August to December prevented a serious breakdown in medical treatment in the British sector. The urgency of the situation justified a departure from the general policy of treating Berlin as a whole in agreement with the other Allies.

The difficulties in getting German production going are well illustrated by the experience with typhus vaccine. The rickettsiae had to be flown from Frankfurt-on-Main, and arrangements were made to obtain 2,000 eggs from outside Berlin. The rickettsiae arrived, but at the last moment the arrangements to get eggs failed. No animals were available to keep the rickettsiae alive so the whole process had to be started again.

Summary

A description has been given of the main medical problems which were met with during the first six months of the British occupation of Berlin. Many more arose—ranging from the de-nazification of the German Red Cross and its reconstitution on democratic lines and the encouragement of learned societies to the tracing of doctors wanted as war criminals, but such subjects are perhaps out of place in an article on health matters.

In September and October a somewhat gloomy view was taken as to Berlin's fate during the winter 1945-6. At the time of writing with the winter more than half over, it would seem that fortune has been kind and the expected epidemics have not occurred.

The following statistics may be of interest in illustrating the improved vitality of a city after the ravages of war.

	Population of Berlin	Birth Rate per 1,000	Death Rate per 1,000	Infantile Mortality per 1,000 Live Births
Pre-war 1939	4,306,500	15.1	14.3	49
During 1944	2,863,600	8.6*	16.2	123

* This figure is low as a large number of pregnant women were evacuated.

Figures are not available from January to June, 1945, but the following are given for the period of British occupation (population, Berlin, British Sector 527,000).

	Birth Rate per 1,000 p.a.	Death Rate per 1,000 p.a.	Infantile Mortality per 1,000 l.b.
July 12-Aug 12	Accurate figures not available		
Aug 12-Sept 12	15	44	231
Sept 12-Oct 12	15	34	231
Oct 12-Nov 12	13	44	168
Nov 12-Dec 12	12	46	246
Dec 12-Jan 12	7	46	246

† This low figure is probably one of the results of the battle for Berlin and the subsequent occupation of the city.

Acknowledgment.—The above description deals with public health matters but the functions of military government are even more extensive than those of a big city in Great Britain. Any progress would have been impossible without the co-operation of all sections of Military Government and of British Troops Berlin. One cannot enumerate the many sections, but the support of the Senior Military Government officer, Brig. W. R. N. Hinde, D.S.O., and the assistance of the A.D.M.S. British Troops Berlin, Col. E. C. Beddows, O.B.E., V.C., made any success attained possible. We would also like to acknowledge the pleasant experience of working with Allied medical colleagues: Col. Pigareff, U.S.S.R.; Col. Freyche, French Military Government; and Lieut.-Col. Scheffer of U.S. Army. As at home, a Health Department does not only depend on medical men. We were fortunate in having Capt. G. H. Chambers, R.A.M.C., and Capt. W. Stapleford, R.A.M.C. (who died while serving in Berlin), as sanitary officers, and Capt. G. Smitham, R.A.M.C., as quartermaster and general staff officer. We would also mention Sgt. V. A. J. Pavitt, R.A., chief clerk, who in addition to his ordinary duties has given great assistance in the revision of this article. Our thanks are also due to Mr. Boucher, O.B.E., and Brig. T. Kennedy, O.B.E., of the Health Branch Control Commission, for their support in the work in Berlin.

NUTRITION OF SCHOOL-CHILDREN IN LEEDS. WINTER, 1943, AND SUMMER, 1944

BY

F. W. CHATTAWAY, M.Sc., Ph.D.Lond.

FRANK C. HAPPOLD, D.Sc., Ph.D.Manch.

AND

A. MARGARET HAPPOLD, M.A.Manch.

Biochemical Laboratories University of Leeds

In order to obtain some idea of the total nutrition of the children in those schools in which we were investigating the nutritional values of the school meals (Bray *et al.*, 1945) we have carried out a survey on the home dietaries by an adaptation of a method commonly recommended. Children in the age groups 8-11 and 11-14 from five schools were interviewed individually during either the winter of 1943 or the summer of 1944. Two of the schools on new housing estates and a third in a poorish-class neighbourhood were examined over both periods. The fourth, examined during the winter period also served in part a new housing estate, and it was changed for one in a poorer district in the summer period. The total number of children interviewed was 150 of whom 60 were seen during the winter period.

The children were selected at random, except that equal numbers of boys and girls were taken in each age group from each school and that a proportionate number of children receiving free meals were included in each selection. It is interesting to note that this random sampling was satisfactory since the proportion of children in the sample taking school milk was the same as the proportion for the whole city. The children were asked individually what they had eaten for breakfast and up to dinner time that day, and for tea, supper, and at other times since dinner the preceding day. They were then shown previously weighed samples of the foods they had mentioned and were asked to select the amounts of the foods they had eaten. A high degree of precision cannot be attributed to the results of this survey, but, on the basis of work carried out with our students, it seems likely that most of the estimates are accurate to $\pm 10\%$, and the results provide an outline of the diet into which the school meal must fit.

In an endeavour to get some spread of meals three groups include Sunday tea and supper the rest being weekday meals. Breakfasts over the two periods consisted mainly of tea but

occasionally cocoa, and bread-and-butter, buns, or tea-cakes, sometimes with jam, dripping, or syrup instead of butter. In the winter period in a few instances a cereal was included, and in a very few bacon or egg; in the summer these foods occurred rather more frequently, and fresh tomatoes and milk were taken in some cases. Most of the children have school milk in the morning, but 7 in the winter and 15 in the summer did not; nowhere did we find anything eaten with the mid-morning milk. Tea consisted usually of bread-and-butter, sometimes jam, tea-cakes, and cake, although chips, meat, sausage, etc., occasionally appeared; and in the summer fresh fruit, mixed salad, cheese, and eggs were also taken by a few. Some had a snack for supper, in which fish and chips frequently appeared, and milk or cocoa. Food on points—e.g., spam, apple rings—appeared only in Sunday teas, and there was a conspicuous absence of cheese in the diets.

Results

In the presentation of results the letter J or S after the initial identifying the school signifies the age groups 8-11 and 11-14 respectively. The standard requirements listed by the United States Research Council are as follows, and we have related our results to them:

Age Group	Calories	Protein	Calcium	Iron
8-11	2,000-2,500	60-70 g.	1.0-1.2 g.	10-12 mg.
11-14	2,500-3,200	70-85 g.	1.2-1.4 g.	12-15 mg.

In the interest of economy of space we have recorded all the collected figures as mean values for each group with their corresponding standard deviations, to indicate the spread of the results within the group. Table I records the adequacy of the

TABLE I.—Proportion in the Group of Diets Adequate in Calories, Protein, Calcium, and Iron

School Group		Calories	Protein	Calcium	Iron
B. J.	Winter, 1943	0/11	3/11	1/11	9/11

P. J.	Winter, 1943	4/12	11/12	0/12	11/12
B. S.	Winter, 1943	0/8	1/8	0/8	4/8
	Summer, 1944	3/11	4/11	6/11	4/11
S. S.	Winter, 1943	0/7	3/7	2/7	2/7
	Summer, 1944	2/12	1/12	2/12	11/12
C. S.	Summer, 1944	6/11	7/11	2/11	11/11
G. S.	Summer, 1944	1/12	2/12	0/12	11/12

dietary in terms of calories, protein, calcium, and iron, and the number of children examined in each group. The original intention was to have 12 in each group, but some results were excluded either by mischance or because we had satisfied ourselves that the particular children were unreliable witnesses. No vitamin values are given, since in our opinion calculations of these values from tables are not yet satisfactory. The vitamin C values for the midday meals were recorded in the previous communication, and in most cases represent by far the greater proportion of this component in the diets.

The results show that during the winter period of 1943 the diets of the 60 children examined were unsatisfactory in calories and protein and generally unsatisfactory in calcium, but (assuming the iron in the diet was readily available) generally satisfactory for iron. The spread of these figures shows that some of the individual diets were most unsatisfactory. The school meals and milk did at least account for 32 to 50% of the calories, 34 to 55% of the protein, 44 to 69% of the calcium, and 31 to 56% of the iron in these diets.

The nutritional position of the 95 children seen in the summer of 1944 was much better, since the mean energy values for the junior children in three out of the four schools visited approximated to the lower standard level of energy intake for this age group, though the wide spread in these results again underlines the low levels of intake of some of the children in these schools. The fourth school (C.L.), which produced such low values, was one of the two schools examined in a poor part of the city, and itself possessed poor facilities for school

meals. It is possible that the lessened intake in this school be a reflection of a lack of appetite related to undernutrition. The energy values of the diets of the senior children were greatly improved over the winter levels, but they are clearly under standard. There was little variation in the levels.

TABLE II.—Energy Values of Diets

School Group	Winter, 1943		Summer, 1944	
	Mean Value (Cals.)	School Meal + Milk (Cals.)	Mean Value (Cals.)	School Meal + Milk (Cals.)
B. J.	1,628 (194)	519	2,149 (394)	727
S. J.	1,944 (299)	703	1,962 (416)	569
C. J.	1,817 (487)	637	2,058 (373)	598
P. J.	1,937 (313)	958	—	—
C.L. J.	—	—	1,682 (388)	533
B. S.	1,687 (254)	723	2,443 (493)	961
S. S.	1,621 (333)	703	1,761 (277)	622
C. S.	—	—	2,491 (404)	1,092
C.L. S.	—	—	1,933 (324)	673

The figures in parenthesis represent the standard deviation.

TABLE III.—Mean Intakes of Protein, Calcium, and Iron

School Group	Winter Period			Summer Period		
	Protein (g.)	Calcium (g.)	Iron (mg.)	Protein (g.)	Calcium (g.)	Iron (mg.)
B. J.	54 (22)	0.66 (0.33)	13.0 (4.6)	58 (26)	1.00 (0.64)	9.1 (3.0)
S. J.	69 (28)	1.20 (0.72)	13.3 (4.2)	55 (17)	0.76 (0.34)	13.6 (7.1)
C. J.	62 (21)	0.80 (0.35)	11.6 (5.7)	68 (38)	0.70 (0.42)	13.9 (7.2)
P. J.	71 (39)	0.76 (0.40)	12.7 (6.8)	—	—	—
C.L. J.	—	—	—	50 (17)	0.69 (0.36)	10.6 (3.5)
B. S.	52 (21)	0.68 (0.33)	13.0 (7.3)	79 (33)	1.37 (0.76)	12.3 (4.0)
S. S.	63 (28)	1.05 (0.72)	12.1 (4.2)	49 (19)	0.72 (0.36)	13.3 (8.4)
C. S.	—	—	—	76 (36)	0.98 (0.47)	17.9 (8.0)
C.L. S.	—	—	—	59 (24)	0.76 (0.42)	14.3 (7.0)

The figures in parenthesis represent the amounts of the various constituents furnished by the school meals and milk.

protein, calcium, and iron within the two periods. The proportions furnished by the school meals and milk to the total diets of the children in the summer period were: calories, 29-44%; protein, 31-56%; calcium, 50-64%; iron, 32-63%.

Conclusion

Without making any sweeping claims from these results or can state: (a) that in the winter period of 1943 many of the children attending these schools were receiving much less than the recommended amount of food; (b) that in the summer period of 1944, with an improved nutritional picture, the standard of nutrition in quite an appreciable proportion was still far from satisfactory; (c) that the value of the school meals and milk in these diets is well justified by the high proportions of the diets furnished through the schools; and (d) when in the summer period the diets had been improved by a marked betterment in the home diets, the school feeding was still providing a high percentage of the total for intake.

Indeed, it is difficult to visualize what the nutrition of many of those children would have been like had it not been for the communal feeding within the schools.

We are indebted to the Director of Education in Leeds and Dr. Willcock, school medical officer; also to Miss Washington for the facilities granted for these investigations. We should also like to record the marked improvement in the school meals which occurred despite a greatly expanding service and under conditions of difficulty.

The Minister of Health, in conjunction with the Secretary of State for Scotland and the Secretary of State for the Home Department will shortly make a new Scarce Substances Order which will come into operation on April 1, 1946. This Order rescinds all earlier Scarce Substances Orders except S.R. & O. No. 795 of 1944, generally known as the Ipecacuanha Order, which is amended by substituting as the authorized alternative for tincture of ipecacuanha a mixture of one volume of tincture of squill and one volume of water.

UNUSUAL GUNSHOT WOUND OF THE INTERNAL CAROTID ARTERY

BY

S. L. SCHWARZWALD, L.R.C.P.S.E.d., L.R.F.P.S.

e unusual development of this case, which remained unsus-
pected from the time of injury to the post-mortem examination.
y warrant recording.

Clinical History

Mr. J. W., aged 33, was injured when handling a small mine which exploded. He was admitted immediately to a near-by hospital. There were abrasions and shallow lacerations, some 3/4 by 3 cm. in extent, on the left temple, 2 cm. from the eye; a small punctured wound just below the angle of the jaw on the left; and several minor abrasions on the limbs. He was shocked and only semiconscious. From the neck wound came a scanty but steady trickle of blood. An exploration was attempted under general anaesthesia, but it had to be abandoned because the patient's respiration became very "difficult" and the threat of asphyxia grew. Intubation was attempted but not accomplished. The presence of glottis oedema was suspected. Subsequently the onset of "cerebral irritation" was noted; his pulse rate rose from 70 on admission to 120 four hours after the operation. A cranio-cerebral injury was suspected, and accordingly he was transferred to Hurstwood Park Hospital. The findings here were as follows.

The patient was stuporous to a marked degree; he opened his eyes and moved on application of pain stimuli and grunted when so roused. Loud speech had a similar effect, but no comprehension was apparent. His general physical condition was moderately good; his pulse rate 90; temperature 99.2°; the respiration stertorous, rather deep, and at a rate of 19 a minute. The blood pressure stood at 160/110, and his cardiovascular system showed no abnormality beyond a bounding pulse and rather loud first sounds. On the left temple there was the wound described above, and a sutured, incised wound with a rubber drain was seen at the level of the upper edge of the thyroid cartilage, extending, parallel to the body of the mandible, nearly as far as the angle of the latter. The neck itself was swollen and distended; the mandibular margin and clavicle were just palpable on the left, and a little more easily on the right. No details such as muscles or trachea could be made out, and the whole swollen neck pulsed with the heart-beat; it was hard to the touch. The sternal notch was obliterated.

The nervous system clearly showed signs of left-sided cerebral damage. The retina of his left eye was detached and located at -20 D, and the eye itself was slightly proptosed. The pupils were equal, central, and circular, the right one reacting sluggishly to light and the left one not at all. There was a diminished reaction to pinprick in the second and third divisions of the right trigeminal nerve, and a right facial palsy of upper motor neurone type. The auditory meatuses were of normal appearance, as were the drums; auditory acuity could not be assessed, but he could perceive sounds on both sides. Apart from weakness of his left sternomastoid and trapezius, which probably had local causes, no further cranial nerve abnormality was found. Both right limbs had an increased muscle tone and were scarcely moved at all even on application of strong pain stimuli; this state of affairs was more pronounced in the arm than in the leg. The reflexes on that side were brisker than those of the other side; knee clonus and ankle clonus were present, and the plantar response was extensor. Curiously enough, sensitivity to pinprick was not as acute on the left as on the right.

The patient could not utter any recognizable words, but only stertorous grunts on stimulation: apart from being aphasic he must have had aphonia as well, due to the local condition of his larynx.

Radiography did not reveal any bony damage, but at the level between C3 and C4 vertebrae, in the neighbourhood of the carotid bifurcation on the left, there was a foreign-body shadow of rugged outline, measuring less than a centimetre across. A lumbar puncture yielded blood-stained fluid under a pressure of barely 100 mm., the fluid soon clotting.

To begin with, the patient's condition did not change much, or only very slowly, for the worse. Eight hours after admission, however, the respiration became quite distressed and loudly stertorous, and his colour was cyanotic; the pulse rate had risen to 140 and the quality was even more bounding than before. Elevation of the jaw did not alter the respiratory distress. On inspection of the larynx it was seen that a good deal of oedema was present and also a hematoma in either ary-epiglottic fold; blood and blood-stained acid had been vomited shortly before.

Endotracheal intubation was performed under pentothal and the distressing signs vanished quickly, the colour improved, and the

pulse rate settled presently to 80. The stupor, however, and all the other neurological signs were, if anything, graver and did not improve: on the contrary, the patient slid back into deepening coma. Within a few hours the pupils were fixed, complete hemiplegia was established, and very little motor response resulted from stimulation of the patient's legs; both plantar responses were now extensor. The pulse rate rose once more, but without the bounding force. Death ensued some 20 hours after admission to this hospital and some 40 hours after his initial injury. The face, and the face alone, showed extreme cyanosis before death.

Findings at Necropsy

Upon dissection of the neck a small amount of blood was found in the opening of the wound and between skin and platysma; the rubber drain, lying in the superficial fascia, led downwards and forwards into an artificial cul-de-sac. The investing layer of the deep fascia showed a very small opening directly under the entry wound, and a track ran from there backwards and upwards, through blood-clot and disorganized muscle; it contained a little semiliquid blood. The whole space between the investing layer, from its attachments above and below, to the prevertebral layer of fascia was filled and distended with clotted blood, which visibly exerted enormous pressure upon all structures within that space. This clotted mass of blood reached upwards to the base of the skull at the pharyngeal tubercle and downwards into the upper mediastinum. It encroached particularly upon the larynx, appearing under the mucous membrane, upon the pharynx, the glottis, and the base of the tongue. The most striking feature was the extent to which the carotid sheaths were compressed, and especially the jugular veins. The lumina of the latter were compressed—considerably so on the right and to almost complete obliteration on the left.

The track ended between the external and internal carotid arteries on the left. At its bottom, exactly in the bifurcation, lay a metal foreign body (mine splinter), measuring 1 by 1/2 by 1/2 cm. The anterior aspect of the internal carotid showed an oval regular opening occupying about one-third of the vessel's circumference. To the upper edge, inside the vessel, there was firmly attached a small amount of clot. It was insufficient to obstruct the blood stream by itself, and inside and about the vessel near the opening fluid blood was actually present.

The brain and its membranes showed a considerable degree of vascular engorgement—again more so on the left than on the right. Macroscopically, the cortex of the left hemisphere showed early softening along the upper edge of the convexity, affecting mostly the Rolandic area. Microscopically, there was practically universal vascular congestion, most noticeable in the capillaries. There was considerable extravasation of blood along the vessels and extensive myelin changes in the subcortical layers. Many cells of the cortex showed pyknosis and some nuclear fragmentation.

Comment on the Findings.—The necropsy report suggests strongly that obstruction of venous return from the head, due to bleeding from the internal carotid artery into the fascial space, was the direct cause of the patient's death. This diagnosis had not been made during life. The smallness of the opening in the enveloping layer of deep fascia, caused by penetration of a high-velocity missile through an elastic membrane, no doubt accounts for this unusual mode of development of a main-arterial injury of the neck; the presence of a rubber drain lying across the unsuspected opening of the real track may conceivably have made things more difficult by helping to occlude the opening in the fascia.

Discussion

Carotid injuries and their serious sequelae have been observed widely during both recent wars, and definite lines of treatment were evolved. To summarize the range of possible events, injury to the main arteries of the neck may be followed by: (1) fatal haemorrhage. (2) Extravasation of blood and rapid formation of a thrombus, with (a) maintained patency of the vessel (embolism may occur at any stage after injury, and the development of a false aneurysm is a common late consequence); (b) quickly or gradually developing obstruction of the injured vessel. Both the latter possibilities expose the cerebral hemisphere concerned to grave danger of partial or complete anaemia, and the severity depends upon the extent to which collateral circulation can be established—a factor depending in turn on anatomical conditions, such as available channels, and also upon time. The danger of embolism falls under a different heading because it concerns the cerebral branches of the internal carotid, some of which, at least functionally, may be considered as end-arteries. The picture, then, resulting from carotid artery injury may range from death to but slight and fleeting hemiparetic signs and symptoms.

As to treatment, repair would seem the ideal; but in most cases the patient does not reach a surgical establishment soon enough,

nor is the technical problem one which can be overcome successfully in a relevant proportion of cases. Thorough exploration and assessment of the injury, in most cases ligation or ligation and division of the vessel, have been largely accepted as the method of choice.

The present case does not comply with the scheme outlined; in retrospect the steady development, step by step as it were, and the persistence of cyanosis of the head after intubation, were the only guides in differentiating the case from other forms of vascular catastrophe in the neck, and this diagnosis could not easily be distinguished in that instance from direct cerebral traumatism, particularly in the absence of a detailed history of the incident.

My thanks are due to Mr. Harvey Jackson for permission to publish this case, and for his advice and help.

CONGENITAL MALARIA

BY

A. ECKSTEIN, M.D.

Professor of Paediatrics, Numune (Model) Hospital, Ankara

AND

W. C. W. NIXON, F.R.C.S., F.R.C.O.G.

Professor of Obstetrics, Istanbul University, Turkey

Opinions are still divided as to the incidence of this disease. Manson-Bahr (1940) states that "congenital malaria is very exceptional, and probably only occurs when accidental tears of the placenta allow passage of parasites from maternal to foetal circulation." In Ceylon, Wickramasuriya, who has had a wide experience of malaria and ankylostomiasis in pregnancy, is of the opinion that pyrexia in children whose mothers have had malaria may be due to transmission of the parasites during pregnancy. It is possible that they are transmitted through the placenta as the result of pathological changes due to the infection. We should go further and suggest that during the intense shivering associated with the ague fits it would be possible for the placenta to be damaged.

One of us (A.E.) has been working for nearly ten years in Turkey and has travelled widely in rural areas, examining children. During this time there were many opportunities for observing the protean nature of the manifestations of malaria from birth to adolescence. The recognition of congenital malaria as a clinical entity needs to be emphasized. The following case, seen by both of us, is of unusual interest.

Case History

Case 1—On July 30, 1944, Sefak Nahi, 20 days old, was sent to the Numune (Model) Hospital, Ankara, because of a pyrexia of 40° C. (104° F.) that had persisted during the previous three days. The infant was well nourished, having been breast-fed since birth. On examination the spleen was found to extend three fingerbreadths below the costal margin. The W.R. was negative, but blood films revealed gametes and ring forms of benign tertian parasites in both mother and infant. The latter was immediately given an intramuscular injection of 0.03 g. of mepacrine (atebrin). The injections were continued daily for six days. The temperature, which on admission was 40° C., fell to 36.5° C. after two days of treatment and had remained below 37° C. since then. By the third day the spleen had diminished in size to two fingerbreadths below the costal margin. The infant was discharged on the tenth day, and the spleen was now only one fingerbreadth. Breast-feeding was maintained throughout.

The mother's history is most interesting. She was 30 years old and had for many years suffered from malaria. She had had five abortions, always in the second or third month. During the present pregnancy she had an attack of malaria at the fourth month. She took mepacrine (0.1 g.) thrice daily for

three days, but did not continue with this for fear of inducing an abortion. After an interval of three days she took pamaquin (plasmoquine) (0.02 g.) daily for three days. The course of her pregnancy was punctuated with attacks of "shivering" and high temperature, for which she received no treatment. The delivery was normal and the baby weighed 3,200 g. (7 lb. 1 oz.).

Further Cases

Two cases of congenital malaria have already been reported (Eckstein, 1942). Four other cases will be briefly described.

Case 2—Baby admitted to hospital when 3 weeks old because of loss of weight. Birth weight 3,950 g. (8 lb. 11 oz.), but had lost 200 g. although breast-fed. Temperature varied between 37.2° and 38.9° C. The spleen had been palpable since the eighth day from birth. Blood film—malignant tertian gametes. W.R. negative. Mepacrine treatment.

Case 3—Baby 2 months old; had had intermittent fever since it was a fortnight old. It was admitted because of anaemia. Temperature varied between 37.3° and 37.8° C. Spleen enlarged to two fingerbreadths below costal margin. Blood film—benign tertian gametes. W.R. and Widal test negative. Mepacrine treatment for six days resulted in a normal temperature and reduction in size of spleen. During the last month of pregnancy the mother had had an attack of fever, and the day after delivery had a rigor.

Case 4—This baby when a fortnight old was admitted to hospital as the mother developed malaria during her confinement and could not breast-feed. On admission the baby was very ill: cyanosed, temperature 38° to 39° C.; spleen 2½ fingerbreadths below costal margin. W.R. negative; blood film—malignant tertian ring forms. Baby died.

Case 5—Baby, one of twins, aged 22 days; brought to hospital suffering from diarrhoea. Temperature, 38.1° C. Splenomegaly—3 fingerbreadths. Blood—benign tertian ring forms. Mepacrine treatment; two days later diarrhoea ceased. The other twin was examined. Its spleen was enlarged; there were no symptoms of malaria except that the blood film showed benign tertian ring forms. This was a case of "occult congenital malaria." The mother had had an attack of malaria in the seventh month of her pregnancy and was treated only with mepacrine for five days. In the last month and immediately after delivery she had pyrexia. Blood—benign tertian ring forms and gametes. W.R. of mother and baby negative.

Commentary

The cases described were brought to hospital in an area where malaria is not endemic. We are of the opinion that where the disease is endemic congenital malaria is not uncommon. The majority of malaria-infected persons in rural areas where malaria is endemic are never seen by doctors. This applies especially to infants who die in their early weeks and never reach hospital. The true nature of their disease is never suspected. The mother when questioned will say that her child died from meningitis, convulsions, coma, diarrhoea, indigestion, anaemia, etc. The clinical manifestations of malaria are of such diversity that it has been described as the great mimic of other diseases. Hughes and Bomford (1944) have re-emphasized this. Such was their experience when dealing with British troops in West Africa. Congenital malaria may be symptomless, as in the second of the twins (Case 5). Occult malaria is one of the varieties of malaria in childhood that are not uncommon (Eckstein, 1943). The existence of such a condition has been known for some time in Turkey, for there is a special descriptive term for it in Turkish—"gizli sitma" (hidden or secret malaria).

We suggest that the high infant mortality could be lowered if adequate suppressive and prophylactic treatment were practised during pregnancy. If a pregnant woman develops malaria she should be given the recognized course of mepacrine and pamaquin (not quinine). During the succeeding months of her pregnancy prophylactic treatment should consist of mepacrine (0.1 g.) thrice a day for two days—for example, Wednesday and Saturdays—in every first and third week.

With regard to the baby of such a mother we would emphasize that, in the event of pyrexia or other clinical features developing, malaria should be immediately suspected and appropriate measures taken. In the absence of pyrexia and if a baby that appears quite normal, one must always remember the possibility of "occult malaria" and examine for splenomegaly. We are not in favour of prophylactic treatment of infants, but only suppressive treatment once the diagnosis of malaria has been made.

The problem of malaria is global. Those authorities who are responsible for the rehabilitation of Europe will find the incidence of this disease assuming astronomical figures. Malaria is one of the greatest scourges in the Tropics and sub-Tropics. The loss of infant life is appalling. It is one of the commonest causes of abortion. Russia, the Balkans, Poland, Italy, Spain, and Holland are countries where the disease may become pandemic. With the shifting of large population groups, districts and countries that have happily escaped hitherto may find themselves faced with this dread disease. The Ministry of Health in England is fully alive to the danger and has issued a circular (January, 1944) warning general practitioners. Without wishing to appear pontifical we should remind those who are responsible for blood transfusion of whole blood, not plasma, of the risk of malaria transmission from donors who have served abroad.

Now that the hounds of war have been leashed there still remains the battle against disease. Combined operations have proved their worth in war. And so in peace it will be the active and energetic co-operation between hygienist, obstetrician, and paediatrician that will reduce the heavy infant casualties from malaria.

Summary

Congenital malaria is not infrequent where malaria is endemic.

Five cases are recorded (including one of twins). Two other cases have already been published.

Prophylactic treatment during pregnancy, and suppressive treatment (0.03 g. of mepracine daily for six days intramuscularly) of the infected infant, are described.

Co-operation between hygienists, obstetricians, and paediatricians is essential for the reduction of infant mortality due to malaria.

HYPERTENSION IN RUPTURED KIDNEY

BY

D. C. CORRY, M.D., F.R.C.S.

Surgeon, the Radcliffe Infirmary, Oxford

Experimental hypertension was first reported by Goldblatt *et al.* (1934) when they showed that by the application of a specially designed adjustable silver clamp which constricted both renal arteries the blood pressure was elevated with only little depression of the secretory function of the kidney. Hypertension was produced by Page (1939) in dogs, cats, and rabbits by enclosing a kidney in "cellophane." The "cellophane" gave rise to a fibrous-tissue reaction which enclosed and compressed the renal parenchyma and by interfering with the blood supply caused hypertension. It is now known that this rise in blood pressure is the result of an enzyme—rennin—produced by the kidney when the blood-flow through that organ is impeded. The rennin acts on a serum globulin—hypertensinogen—to produce a pressor substance, hypertensin. A series of 198 cases of nephrectomy for hypertension in chronic unilateral renal disease was reported by Braasch (1942). In 65 of these the blood pressure at the end of a year was still normal.

During the last four years I have seen five cases of recent renal injury, and in four of these there was a raised blood pressure lasting some days. During this period seven other cases of ruptured kidney were admitted to the Radcliffe Infirmary. The blood pressure was not taken in five cases. The other two cases each had one recording of the blood pressure; in one of them it was raised.

Records of 4 Cases

Case 1.—November, 1941. A boy aged 15 had an injury at rugby. Seen four hours later, there was gross haematuria; pulse 100, blood pressure 160. Some rigidity was present on the left side and a haematoma could be felt. Expectant treatment was given, and the blood pressure fell to normal in three days. An intravenous pyelogram taken a month later showed that both kidneys were normal.

Case 2.—On Dec. 31, 1944, a man aged 25 slipped and fell flat on his abdomen. There was pain in the right loin, with haematuria. On Jan. 2, 1945, he was admitted to Radcliffe Infirmary with gross

haematuria; blood pressure, 170/110. There were rigidity of the left side and increased dullness in the left flank. Jan. 3: Urine clear; blood pressure, 150/95. Jan. 8: Blood reappeared in urine, and persisted for two days. Jan. 23: Intravenous pyelogram normal; blood pressure, 120/80.

Case 3.—A boy aged 4 was struck in the abdomen by a tractor-driven wagon on March 4, 1945. Haematuria occurred the same day. He was admitted to Radcliffe Infirmary on March 5 with haematuria, and rigidity and tenderness in the right renal region. Blood pressure: Morning, 170/110; evening, 150/70. Haematuria occurred during the day, but an evening specimen of urine was free from blood. March 6: Blood pressure, 130/70; no haematuria; no rigidity. March 12: Blood pressure, 110/80.

Case 4.—On Nov. 17, 1945, a young man aged 19 was injured at rugby. He was admitted three hours later with pain in the left loin and haematuria. There was rigidity in the left flank; no haematoma was felt. Haematuria persisted for 6 days. Nov. 18: Blood pressure, 140/90; this pressure persisted for a week. Nov. 25: Blood pressure, 130/85. Nov. 27: Blood pressure, 120/80. An intravenous pyelogram taken two months later showed normal kidneys.

Comment

A raised blood pressure occurs in some cases of ruptured kidney, and returns to normal after some days. This pressor effect is not dependent on the formation of a perirenal haematoma. The only clinical application is that if the blood pressure is raised it rules out associated injuries such as ruptured spleen.

Medical Memoranda

Penicillin Treatment of Malignant Diphtheria

While diphtheria is listed as one of the conditions for which penicillin may be given, we have so far seen only one report of its use (Symons, 1945). The following two cases may therefore be of interest. Both were caused by the intermediate type of diphtheria bacillus, and in each case the organism was sensitive to penicillin, as proved by laboratory tests.

CASE I

A boy aged 15 was admitted to hospital on April 18, 1945. He had typical bull-neck diphtheria, and his parents had at first thought he was suffering from mumps. Membrane covered tonsils and uvula, and there was marked nasal discharge; haemolytic streptococci grew in both nose and throat cultures, as did diphtheria bacilli.

On admission he was given 40,000 units of diphtheria antitoxin intravenously, and 40,000 units intramuscularly. Next day a further 40,000 units was given intravenously. On admission sulphamizide, 1 g. four-hourly, was given, being continued for four days. On April 20 he received 50 mg. of vitamin B, and 500 mg. of vitamin C intramuscularly, and these injections were repeated daily until May 4, when vitamin therapy was continued by mouth. On April 20 petechiae were noticed around the base of the neck and on the upper chest, and it was decided to try penicillin. He was given 100,000 units daily by three-hourly intramuscular injections for five days. A spray containing 500 units per ml. was also used locally on the throat, hourly while awake.

Two days after starting penicillin therapy the throat was clear of membrane apart from one small speck on the uvula, and we were struck by the rapidity with which this very bad throat had cleared. His subsequent progress was uneventful except for some complaint of blurred vision during one day in his fourth week. He was allowed up on June 20, and showed no sign of any other complication.

CASE II

A youth aged 17 was admitted on May 12, 1945. On the evening of May 8—VE Day—he had been out all night celebrating, and on the evening of May 9 was on duty as a page-boy, so that his illness was not more than three days old on admission. He had massive bull-neck adenitis, especially on the right side, where the swelling extended over the parotid region. There was a mass of membrane smothering the right tonsil and extending forward to within half an inch (1.25 cm.) of the incisor teeth. The uvula was coated but was difficult to see, and the left tonsil was embedded in oedema. Swabs showed both haemolytic streptococci and diphtheria bacilli.

He was given 40,000 units of antitoxin intramuscularly and 60,000 units intravenously. Penicillin was started on the day of admission—100,000 units daily for six days. Penicillin spray, as in the first case, and vitamin injections were also given. The patient was very restless and required morphine for the first few days to give him rest. On May 14 his condition was unchanged: the contour of the throat was very difficult to make out, as a large lump of thick membrane was hanging down from the hard palate. This separated later that day, and was so extensive that we felt that mucous mem-

brane had been sloughed, but section proved this was not the case. On May 20 immobility of the palate was noticed. On May 22 he had attacks of vomiting, the pulse rate was very slow, and there were occasional extrasystoles. These attacks continued until May 24, when the pulse rate was about 30 and the blood pressure 85/60. The patient died on May 24—a typical case of early cardiac failure.

DISCUSSION

Had we had only the first case under treatment we should have been inclined to think that penicillin had had a dramatic effect. The appearance of petechiae is usually regarded as an ominous sign. There is a high mortality in such cases, and those that recover usually have a hazardous passage: in this boy the striking features were the rapidity with which the membrane cleared and the almost complete absence of complications.

On the other hand, we have occasionally seen patients quite as ill, including one with haemorrhages from nose, throat, and rectum, who have recovered with very few complications on antitoxin and vitamin therapy. Also against too ready an acceptance of the effect of penicillin is the complete failure in our second case. It is possible that increased dosage might have helped. Symons (1945) gave almost double the dose in his successful case. He was convinced on clinical grounds, by the "most unusual, unexpected, and rapid disappearance of the extent of gelatinous membrane," that penicillin saved his case of bull-neck diphtheria. His description corresponds fairly well with our first case.

We are indebted to Dr. J. S. B. Penfold, who carried out the bacteriology, and to the medical officer of health for Southend-on-Sea for permission to publish.

Sigmoidoscopy: Perforation of the Rectum

In view of the many cases which to-day require sigmoidoscopic examination, the following notes may perhaps be useful, since they emphasize one risk of this procedure which is so well known as to be almost ignored.

CASE RECORD

An Italian prisoner of war aged 28 was admitted to a British military hospital with a history of having had amoebic dysentery in 1941. Since then he suffered from bowel irregularity, which had recently become more troublesome. A routine sigmoidoscopy was done at 9 a.m. by the Italian medical officer in charge of the case. This medical officer, who is experienced and competent in this form of investigation, noted that no blood or mucus was visible, but that at 8 in. (20 cm.) there were "two small superficial ulcers." It was recorded that at 6 p.m. the patient complained of some abdominal pain and his temperature was 99.8° F.

The surgeon specialist was called to see the patient the next day at 1 a.m., and found him very ill—pulse 130, respirations 60, and temperature 100.6° F.—and in considerable distress. The abdomen was much distended, tympanic in all parts, generally tender and rigid, and silent to auscultation. Laparotomy was done at 11 a.m. under general anaesthesia. On incising the peritoneum a large volume of gas whistled out and the distended parietes collapsed like a pricked balloon. The peritoneum of the small gut and parietes were dark red and injected. The pelvic contents were bathed in thin foul-smelling pus and the depths were sealed off by plastic incisions of bowel and omentum. About 2 in. (5 cm.) above the ileo-vesical fold the anterior wall of the rectum showed a narrow darkly stained area of peritoneum extending horizontally half-way round the circumference of the bowel. Patches of similar appearance were seen in the caecum and lower sigmoid; in these two places the wall of the bowel did not appear to be thinned, but that the rectum was actually perforated by a small tear near its centre; through this gas and liquid faecal contents bubbled on any manipulation. This tear was closed by three Lambert sutures, and these were buried by a flap of oversewn omentum. A colostomy would have been difficult without freeing the bowel and exposing extraperitoneal issues, so a caecostomy was carried out; a large drainage-tube was put into the pelvis, and after the patient had returned to bed a tube was passed through the sphincter and secured by a stitch.

The patient's convalescence was stormy and precarious. Collapse of the left lung became manifest after 24 hours. Immediately after operation an intravenous glucose-saline drip and stomach suction were instituted. He was given 18 ml. of multivalent anti-gas-angrene serum at once. Sulphathiazole therapy was started after 4 hours, 36 g. in all being given. The abdominal tube discharged foul-smelling pus profusely, but the wound itself united well. Cysts of *Entamoeba histolytica* were found in the caecostomy fluid on the fourth day. The abdominal drainage-tube was removed on the fifth day, but discharge continued through the sinus for 21 days. The caecostomy tube came away on the sixth day and the stoma healed without further discharge. The bowels moved normally on the seventh day, when the patient became, and remained, afebrile. The routine treatment of the amoebic infestation was begun on the sixth

day after operation, and from the eleventh to the fourteenth day 10 g. of sulphaguanidine was given daily by mouth.

It was considered that in all probability air inflation during the sigmoidoscopy, and not direct injury with the instrument, caused the above lesion.

H. B. WALKER, F.R.C.S.,
Major, R.A.M.C.; Surgical Specialist.

Volvulus of Small Intestine

In view of the recent communications on cases of intussusception and volvulus, I feel that the following case is worthy of note

CASE RECORD

Mrs. A., a Jewess aged 39, was admitted here on Nov. 26, 1945, at 4.15 p.m., having collapsed in a shop about half an hour previously. She had already been seen by a general practitioner, who had administered 1/3 gr. (22 mg.) of omnopon to allay her severe abdominal pain, which had started suddenly and gradually increased for about half an hour previous to her collapse. On questioning, the patient stated that she had a constant sharp pain in the upper and middle abdomen which passed through to the back at the same level and was unrelieved by the injection. She had had no other similar attacks. The bowels were constipated and micturition was normal; she was nauseated but had no vomiting. In 1938 she had undergone Caesarean section, and during the past month had been treated with antuitrin-S for menorrhagia, but her last injection in this course had been nearly one week before admission.

On examination areas of tenderness to palpation were elicited in the epigastrium, in both iliac fossae, and in the left costo-vertebral area. There was no rigidity, guarding, or palpable masses. Heart and lungs, N.A.D.; T. 101.6° F.; P. 80; R. 24; B.P. 175/80; urine normal. A pelvic examination was abandoned because of severe shivering. Four hours later her pulse rate had increased to 90 and her B.P. was 160/80. There had been no more shivering, but the patient had vomited twice. The abdomen was tender below the xiphisternum and in both iliac fossae. A bulky uterus was the only abnormality noted on vaginal examination.

Laparotomy was decided upon, and the abdomen was opened in the right paramedian line under spinal analgesia after an intravenous drip had been started. By this time the B.P. was 140/70. Some blood-stained fluid was found in the peritoneal cavity and several enlarged tense black coils of twisted small gut were delivered. A volvulus of the small intestine was diagnosed and the gut was untwisted through almost a complete circle. The remaining part of the twist could not be undone, and the cause was found to be an irreducible intussusception involving the distal ileum to within 6 in. (15 cm.) of the ileo-caecal valve. Nearly two feet (60 cm.) of small gut was resected and enough terminal ileum remained to perform a side-to-side anastomosis. The peritoneum was closed without drainage and the patient returned to the ward. Intravenous therapy and gastric aspiration were continued for four days. The patient made an uneventful recovery, and was discharged 18 days later to complete her convalescence at home.

On examination of the specimen after operation no cause for the intussusception was found, although a Meckel's diverticulum had been confidently sought. (See accompanying photograph.)

T. A. O'QUILLIAM,
St. Charles' Hospital, N. Kensington, M.B., B.S., M.R.C.S., L.R.C.P.

The Minister of Labour has made regulations entitled the Patent Fuel Manufacture (Health and Welfare) Special Regulations, 1946, which provide for the observance, in patent fuel works, of various specified requirements with regard to ventilation, the suppression of dust, washing facilities and clothing accommodation, medical supervision and examination, the protection of the eyes and skin of work-people, and messrooms.

Reviews

SYMPTOMS OF VISCERAL DISEASE

Symptoms of Visceral Disease. A Study of the Vegetative Nervous System in its Relationship to Clinical Medicine. Sixth edition. By Francis Marion Pottenger, M.D., F.A.C.P. (Pp 442, 87 illustrations and 10 colour plates 25s.) London: Henry Kimpton.

This book was first published in 1919, and seems therefore to have established itself firmly in medical literature. The author begins by describing the anatomy and physiology of the vegetative nervous system, the effect of the ionic content of the cells on nervous responses, and the reaction to various drugs. The reflexes arising in health and disease are described, and this leads to a general discussion of the phenomena of disease. The innervation of the important viscera and the reflexes and symptoms arising from them are finally studied in detail. The general thesis of the book is the idea that most symptoms can be explained as disturbances in normal reflexes. When Mackenzie preached this idea a generation ago it seemed so stimulating that it is puzzling that we are so little interested in it to-day. Dr Pottenger's book is avowedly a study of man as a segmented organism and the whole trend of biochemistry and psychology in these last years has been away from neural segments to cells and ferments in the one direction, or to the total organism in the other. Moreover, we have been more interested in the aetiology and prevention of disease than in the mechanism of symptoms. It seems probable, however, that the development of psychosomatic medicine will give a new impetus to the study of symptoms, and workers in this field will find Dr Pottenger's book a valuable source of information.

VITAMINS IN MEDICINE

The Vitamins in Medicine. By Franklin Bucknell, D.M., M.R.C.P., and Frederick Prescott, M.Sc., Ph.D., M.R.C.S. Second edition, revised and enlarged. (Pp 916, illustrated 50s.) London: William Heinemann Medical Books, Ltd. 1946.

It is good evidence of the value of a book that a second edition is required within four years of the publication of the first. The authors of *The Vitamins in Medicine* have found much fresh material to add to their book, particularly in connexion with the vitamin B complex. There are claims in the literature for the existence of 22 members of the B complex, eleven having been identified chemically. The existence of the rest has been recognized from animal feeding experiments, though some of these indicate the probable identity of certain vitamins which have been given different names by different workers—e.g., B₁ is probably the same substance as B₆, pyridoxine. The subject of riboflavin alone occupies 69 pages (31 in the first edition) and nicotinic acid 68 pages (41 in the first edition). Other chapters also have been enlarged somewhat. A chapter has been added on essential unsaturated fatty acids and other minor fat-soluble vitamins. No evidence of a shortage of unsaturated fatty acids in human beings has been found yet. Only two other "minor" fat-soluble vitamins are at present thought to have been found—a growth factor in butter, active on calves and rats, and an antistiffness factor in greens and raw cream active on guinea-pigs. The tables of vitamin content of foods have been revised and the numbers of references to original papers and of illustrations have been brought up to nearly 4500 and 208 respectively. Both the authors and publishers may be congratulated on producing a very fine work.

PATHOLOGY OF TUMOURS

Kettle's Pathology of Tumours. By W.G. Barnard F.R.C.P., and A.H.T. Robb-Smith, M.D. (Pp 318, illustrated 21s.) London: H.K. Lewis and Co.

In the first edition of this book, published in 1916 E.H. Kettle set out to "provide a manual for students which should contain the generally accepted teaching on the pathology of tumours without the mass of detail proper in a more ambitious work of reference." His efforts achieved this object and a great deal more. His book, stamped with the impress of his personality and illustrated by his own hand, crystallized years of wide and accurate observation in a relatively small and beautifully written monograph.

The authors of the new edition express the hope that its publication may keep Kettle's name fresh in the minds of

students of pathology. They have attempted—and have succeeded—to preserve as much as possible the character and happy phraseology of the earlier editions, and from recent studies in experimental and histological researches have selected those most likely to form permanent additions to knowledge. It is indeed gratifying to find how well the original character of Kettle's work has been preserved, and to be able to recommend this edition to students as a sound, reliable, and clearly written introduction to tumour pathology.

THE CRIMINAL PSYCHOPATH

Rebel Without a Cause. By Robert M. Lindner, Ph.D. Introduction by Sheldon Glueck, Ph.D., and Eleanor T. Glueck, Ed.D. (Pp 259 21s.) London: Research Books Ltd. 1945.

This is one of a series of research studies dealing with psychiatric problems. Its subject is a young man serving a long prison sentence who would be diagnosed by most authorities as a criminal psychopath, a group well recognized as extremely resistant to treatment and as to whose psychopathology there is no agreement. This patient is a recidivist who has continued to commit many crimes from an early age, ranging from petty larceny to attempted murder. No punishment had any effect and until the successful treatment described in this book he was obviously heading for a continuous career of crime. He also suffered from a severe blinking tic of his eyes supposedly dating from an attack of measles in very early childhood. By means of a concealed microphone the author has secured a verbatim record of 46 hours of analysis. This was not entirely orthodox psychoanalysis, as from time to time the patient was put into deep hypnosis, during which deep-seated memories were elicited which were afterwards rediscovered while the patient was conscious. In this way we could be fully understood by him and integrated into his conscious personality. The result is of great interest since it would seem that memories dating from the 7th or 8th month of life were restored, the operative event being observation of parental coitus, with consequent development of a full fledged Oedipus complex and fear of castration, culminating in the attempted murder of a father surrogate. As a result of treatment not only was the ocular tic cured but the whole attitude to life of the patient was changed. It may be noted that the use of hypno-analysis reduced the duration of treatment to 46 hours which is much less than would have been required for an orthodox psychoanalysis.

The author points out the uselessness of the ordinary penal treatment of these psychopaths—a conclusion with which we should all agree. The subject of this account is one of six treated in the same way, and it would appear that the procedure holds out definite promise that such intractable cases might be successfully dealt with by these means which, though still lengthy and difficult, are not outside the bounds of possibility. All those concerned in psychiatric and medico-legal problems should read Dr Lindner's book with care, and they will be rewarded by a fascinating clinical study.

Notes on Books

The 73rd annual volume of *Whitaker's Almanack*, for 1946, has now been published from 13, Bedford Square, London, W.C.1. It includes a chronicle of the war from the invasion of Poland to the unconditional surrender of Japan, also the results of the General Election of 1945, with the new Ministry and newly elected House of Commons. These and other additions of current interest swell the book beyond its former limits. It is published in three editions: the complete edition, cloth bound, with 1,088 pages, at 12s. 6d.; the abridged edition, in paper covers, with 704 pages, at 7s. 6d.; and the library edition, bound in leather, with 13 coloured maps, at 25s.

The text of the second edition of *Modern Anaesthetic Practice* (Eyre and Spottiswoode Ltd., 12s. 6d.) has been completely revised. In spite of variations in style and detail inevitably attendant on multiple authorship, the advice is everywhere sound and can be safely followed by the occasional anaesthetist. As is right in a book not intended for specialists, practical details predominate, and no attempt is made to lead the reader into academic byways.

A booklet of *Hospital Prayers* was compiled in response to an instruction of the General Assembly of the Church of Scotland in 1944. It is printed by William Blackwood and Sons, Ltd., of Edinburgh, for the Committee on Public Worship and Aids to Devotion. The price is 1s. 6d., and Part I (which may be had separately, being chiefly for use by patients) costs 9d.

Nova et Vetera

CESALPINO AND THE CIRCULATION

The Circulation of the Blood and Andrea Cesalpino of Arezzo. By Dr. John P. Arcieri. (Pp. 193; illustrated. No price given.) New York: S. F. Vanni, 30, West 12th Street. 1945.

Dr. Arcieri is an Italian who has long practised in America. He is well known as a passionate claimant for the importance of Italian civilization. Few can believe that the unique part of Italy in the revival of learning needs advocacy, but, since nationalism is bedevilling the world, the reviewer must treat such feelings with all tolerance. Dr. Arcieri revives for the fiftieth time the claim for Cesalpino (1519-1603) as discoverer of the circulation. He holds that an underhand designing knave, William Harvey, cunningly and basely filched his due honour.

The facts are these. Scattered in the works of Cesalpino, and notably in his *Peripateticæ Quaestiones* (Venice, 1571 and 1593), are passages which, when placed together, can reasonably be regarded as an unclear expression of a belief in the circulation. The lesser circulation had, as is well known, already been enunciated by Servetus and Columbus. It is also now well known that an Arabic writer in the 13th century had guessed at the circulatory movement of the blood as a whole and expressed it clearly. Harvey possibly gained a hint from the work of Cesalpino. Certainly he attended lectures by one of his pupils. Scientific investigators are, in general, eminently receptive of suggestions. Cesalpino, however, did not stress the circulatory idea, or found any doctrine or practice on it, or support it by experimental proof, or give it a prominent place.

Now science is not "bright ideas." If it were every sixth form would contain several scientific geniuses. Nor is it a grand scientific merit to make suggestions. If it were Plato would constantly be studied by students of geology and Lucretius by students of chemistry. Science is the process of demonstration by carefully described experiment and/or observation and the making therefrom of such deductions as lead to further demonstrations. That is where Harvey comes in. That is where Cesalpino goes out.

It is not the historian's task, or indeed within his power, to place scientific figures in order of merit. Cesalpino was a very able man cursed by an obstinate philosophic conservatism and a poor literary style. In these respects he resembled Harvey. His scientific interests were wider than Harvey's. Beside his medical writings he made significant contributions to the nascent sciences of mineralogy and botany. To mineralogy Cesalpino contributed *De metallicis* (Rome, 1596), which is a basic work for modern crystallography. Moreover, he had a pupil, Mercati (1541-93), who predeceased him but whose beautiful *Metallotheca* (Rome, 1717), published long after, carried on the master's tradition. In botany Cesalpino's *De plantis* (1583) contains the first attempt at a "natural" classification of plants, which leads through Joachim Jung, Bauhin, and Ray to Linnaeus, as has been generally acknowledged by botanists. Cesalpino is thus an important if secondary figure in an age of scientific giants Copernicus, Vesalius, Galileo, Stevinus, Kepler, Descartes, etc. In the reviewer's judgment Harvey too is below the rank of these, since, though a superb experimenter—which Cesalpino was not—his field was relatively narrow, he lacked wide generalizing power, could not free himself from Aristotelian prejudices, and was backward in philosophic outlook.

We would place the total achievement of Cesalpino as high as does Dr. Arcieri. Unfortunately that ardent advocate of everything Italian devotes most of his not unuseful book to unmasking a supposedly widespread Anglo-American plot to belittle Cesalpino. But the difficulty of historians is to give exact meaning to what Cesalpino did say on the circulation. In his last work he bursts into sudden and unexpected clarity with the statement: "The fount of the blood in the heart is distributed into four vessels—namely, the cava, the aorta, the pulmonary vein, and the pulmonary aorta—[and] irrigates the whole body like the four rivers going forth from Paradise." This seems a plain contradiction of a circulatory doctrine.

In denying that this is so Dr. Arcieri places his hero in the position of a famous Cambridge character:

"There once was a man on a syndicate
Who arose his opinions to vindicate;
He wished to deny
That he meant to imply
The ideas which his words seem to indicate."

In truth Cesalpino was not quite sure himself what he meant about the movement of the blood. Such vague uncertainty is common among scientific pioneers. But on this matter Harvey was sure, and that is his special merit.

We must all try to keep our tempers, and the reviewer is confident that, for the blessing of peace, all his fellow conspirators will gladly accept Dr. Arcieri's estimate of Cesalpino on other matters. They would prefer that he should not defame the character of Harvey if they cannot persuade him of his scientific merits. As to his treatment of their own character they will, he is sure, show themselves much less sensitive.

GEORGE OWEN: PHYSICIAN TO HENRY VIII

What little is known about Owen will be found in Munk's *Roll of the Royal College of Physicians*. He has been credited with having performed Caesarean section on Jane Seymour at the birth of Edward VI. It is known that in company with Sir William Butts (then Dr. Butts) he signed a report on the Queen's health on Oct. 24, 1537. Here is an early example of antenatal care. Henry was desperately anxious to have a legitimate male offspring and may have been genuinely concerned about the Queen's health. Jane Seymour died in childbirth later in the year 1537. Perhaps the operation was performed at the point of death of the mother.

Owen was born in Worcester diocese and was educated at Oxford. Doubtless he was of Welsh ancestry. The King appointed him an executor of his will and left him £100. He died on Oct. 18, 1558, and was buried in St. Stephen, Wallbrook. From the State Papers of the period we learn that he received considerable grants of monastic property, much of which had belonged to Abingdon. He had also an annuity from St. Augustyne's, Bristow (Bristol), in 1542. In the same year he had a licence to alienate the meadow called Bewley Mede, on the N.W. side of the stone causeway leading from Osney Bridge to the new bridge over Bulstake water, to Robert Morwent, Clerk. This is one of several licences obtained at this time, and he appears to have had a part interest in the lordship of Cumnor Place in company with John Bridges, M.D.

Owen's will (P.C.C. Chaynan 11), dated 5. Philip and Mary (1558), was proved May 26, 1559. He left his "Soule to Jesus Christ. Body in the earth. To my wif all such stuff and goodes as in her house at Marten and here in London: my plate that I had before I was marryed onely excepted. Sonne William, Goddes blessing and myne. Sonne Edward £10 yerely at hands of Sonne Richard and to be ruled by him till 24. Daughter Lettice £100, to have meate and drynke with my sonne till she marry. I forgive Henry Jusse debts and rents due. To Thomas Crowe reversion of Galburys hole at Whatley, paying £4. To Ryse reversion of Harparishold at Woolvercot. Henry Colley and John Lambe a hole yeres wages William Jonys 20/- Lewes, my bayly, half a yeres wage. Mister Collins, a white mare. To Woolvercot church a young cowe to be put to some use that I may always be prayed for." The will was witnessed by John Collins, priest, and Henry Jusse, of Yarnton. The executors, Sonne Richard Owen, Mr. Secretary Boxall, Mr. Wendy, and Sir Leonard Chamberlayne, were empowered to sell land at Chorlton, Watly, Fincote, and apparently his wife's manors of Budcombe and Congresbury. Of these Wheatly, Woolvercot, and Yarnton are all near Oxford. Chorlton I imagine is Charlton-upon-Otmore, also in Oxfordshire. Congresbury is in Somerset.

What lies behind the queer legacy to Sonne William: was he already provided for, or had he been an unruly, troublesome son? I much fear the latter. And the legacy of the young cow to Woolvercot Church is most unusual. Had it been with the idea of keeping the churchyard cropped, a few sheep would have been better. Did he contemplate a supply of free milk for the children? One would like to know, but I cannot offer an explanation. We have all heard of parish bulls, and those who are fond of *Tristram Shandy* will remember that Mr. Walter Shandy, "whether by ancient custom of the manor, or as impropiator of the great tythes, was obliged to keep a bull for the service of the parish"; but this was a manorial matter, not an ecclesiastical, and had Owen wished to leave a memento to the parson he would surely have been more definite. I suspect that the John Collins, priest, who witnessed the will left the white mare for his legacy.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 23 1946

HOW LONDON SAW IT THROUGH

Population statistics, like weather forecasts and other useful or interesting information, were withheld during the war, and now that the figures can be released they furnish some surprises. For many years, even since the beginning of the century, the population of the county of London has been regarded as four millions or so—in the middle 'twenties it reached four and a half millions—though even before this last war it was declining in favour of Middlesex, Surrey, and Kent; but it comes as a shock to realize that, according to the Registrar-General's estimate, the population of London in the war years fell to two and a half millions. Those who lived in London throughout the war were hardly conscious of the absence of so large a number of their fellow-citizens, but evacuations, official and unofficial, were larger than might have been supposed. The general death rate mounted during the war, but such was the solicitude for the child and its mother that in spite of all adverse conditions the infant mortality in 1944—namely, 51 per 1,000 births—was considerably lower than the average (57) for the years 1936–40, and the maternal mortality also declined to 1.70 in 1944 from 2.02 in the earlier period. The maternal death rate was the lowest recorded; the infant death rate was the lowest except for 1942, when it was 50. This is the more remarkable achievement when it is remembered what disorganization resulted in London from air attack, how frequently antenatal care must have been interrupted, and how uncertain must have been the booking of maternity beds. As for the commoner infections—measles, scarlet fever, diphtheria, and whooping-cough—the mortalities were minimal, the highest in all the war years being for whooping-cough in 1944, when the deaths numbered 0.05 per 1,000 of population. In that same year there were only seven deaths from scarlet fever and seven from measles; this in a child population which even in the evacuation period must have numbered three-quarters of a million. A condition which leads to a disquieting number of infant deaths is diarrhoea and enteritis. There were 427 deaths from this cause in 1944 among children under 2 years of age. This rate has increased since 1939, and research is being undertaken into the reasons for its persistence.

The interim report for 1944 of the County Medical Officer of Health for London¹ reveals for the first time, for each of the metropolitan boroughs, the number of deaths due to enemy action during the entire war period. The total death roll in the air raids was 17,811—almost equal to the entire population of the borough of Holborn. The peak year was 1940, with 7,793 deaths, but 1944, with

its flying bombs and rockets, took a further toll of 4,567 lives. It was sometimes said, loosely, that the chance of being killed in a raid was not greater than the chance of being killed in a street accident, but in fact during the war years there were ten times as many fatal casualties in raids as there were due to vehicles on the roads.

The story of the hospitals in the raids is a proud one and deserves something better than ephemeral record. There were 660 county hospital "incidents" altogether, and hospital accommodation providing beds for 5,000 was totally destroyed. During the flying-bomb and rocket period alone hospitals were damaged on 138 occasions. The number of patients killed was 257, and of staff 62. "No matter what happened," says Sir Allen Daley in this report, "staff of all grades were undaunted and showed an example of unquenchable spirit, high morale, and devotion to their task of attending the sick and injured, the memory of which will never leave those who were responsible for ensuring that the service did not fail." The patients, too, showed a fortitude, even a defiance of the terror, which was remarkable. A special word of praise is due to the ambulance men, who carried on though several of their stations were destroyed and the lives of some of them were lost; and to the hundred or so domiciliary midwives employed by the L.C.C., about half of whom had their homes wrecked or damaged, yet no woman in childbirth went unattended. The school medical service carried out its normal functions, and in addition, in 1944, was responsible for the pre-evacuation inspection of 118,000 children. This later evacuation brought no complaints from the receiving centres.

On the preventive side the report gives particulars of the mass radiography service, carried out at six centres. As a result of 46,671 miniature films taken during the year, 1,795 persons were called for further investigation, and among them 355 showed apparently active tuberculous lesions. The diagnosis was confirmed by the tuberculosis officer in 298 cases; 28 were doubtful, and the remainder refused investigation or were awaiting further report. Attendance at the venereal diseases clinics for men has fallen consistently during the war years, and at those for women less consistently, but this, as is well known, does not denote a general fall in incidence. It is due mainly to the absence on war service of a large proportion of the population of the ages at which exposure to infection is most likely. During 1944 there was a large increase in the number of alleged contacts reported under Defence Regulation 33B, and in some cases contacts were traced and were persuaded to undergo examination. Only 14 contacts were prosecuted for failure to attend for examination or to submit to or continue treatment.

One further fact, characteristically British, may be noted. During all the upheaval of the flying bombs and evacuation a highly successful medical society was formed with 300 foundation members, all of them medical officers of the L.C.C. staff. The aim of the society is to encourage contact between medical staffs of county hospitals and of neighbouring municipal and voluntary hospitals and general practitioners, and to give opportunity for the discussion of clinical problems.

CONTRACEPTION AND INFERTILITY

The possibility that semen from the male may have effects, other than fertilization of the ovum, on the female organism has long interested members of the medical profession and others. It has many practical implications which from time to time have attracted questions from readers of the *Journal* and discussion in our correspondence columns. Kohlbrugge's theory that the products of degeneration of spermatozoa are absorbed by the uterine glands and exert an endocrine action in the female, possibly accounting, among other things, for the fact that a woman in the course of years becomes more and more like her husband, is now discredited. (Hartman¹). The old doctrine of telegony, which supposed that the offspring of a female animal might resemble not the father but an earlier mate whose semen had had a permanent effect on the mother, has been "relegated to the limbo of folk-lore" (Hartman¹), though at one time it was regarded as a possibility by biologists of eminence. Then came the demonstration of the production of spermatoxins consequent upon the parenteral administration of semen to the female, and it was postulated that in some circumstances these might develop as a result of the frequent deposition of semen in the vagina, and thus temporary sterility of the female might follow repeated coitus. Some have held this theory to account for the occurrence of pregnancy when the partners of a previously infertile marriage are reunited after a long period of separation. The results of animal experiments on the production of spermatoxins and consequent sterility, which are reviewed by Hoffman,² are generally regarded as inconclusive. The occasional occurrence of pregnancy in the circumstances stated above can be accounted for in other and more rational ways.

In more recent years it has been suggested that some of the chemical constituents of the seminal fluid, rather than the spermatozoa themselves, are absorbed by the vagina and are of value to the female organism. It is said that women experience a sensation of well-being as a result, and it is even alleged that sometimes the odour of semen can be detected in the breath of women after coitus (Van de Velde³). Such statements are largely unsubstantiated, but in 1943 Green-Armytage⁴ reported the results of a series of experiments in which immature rats and rabbits were injected with human semen. He found that the uteri of the animals responded by hypertrophy, and concluded that human semen contains some hormone (? testosterone) which, when absorbed by the vagina, is of importance in promoting full development of the female genitalia. From this it was argued that those methods of contraception which prevent the semen from coming in contact with the vagina (e.g., coitus interruptus, condom) are harmful in that they hinder full uterine development and may therefore result in sterility or lowered fertility. Although Green-Armytage's interpretation of his experimental results, and the clinical significance applied to them, have not been generally accepted, the matter has remained *sub judice*.

The position now appears clarified by the work of Bacsick, Sharman, and Wyburn,⁵ who have recently repeated Green-Armytage's animal experiments and have failed to confirm his original findings on which the argument was based. They injected human semen repeatedly over varying periods into immature female rats, rabbits, and guinea-pigs, and also adult spayed guinea-pigs, controlling their experiments by animals of similar state, some of which were untreated and some treated with testosterone. The vagina, uterus, and ovaries were in each case examined for responses, and it was found that the injection of semen into the immature rats and rabbits had no effect at all on the genitalia. In the immature and adult spayed guinea-pigs there was some increase in the size of the uterus, but the authors point out that this finding is open to several interpretations and is by no means proof of hormonal activity on the part of the semen. In no case was the effect comparable to that of testosterone, and the conclusion drawn from these experiments is that there is no evidence that human semen contains either androgenic, oestrogenic, or gonadotrophic hormones. Bacsick and his colleagues not only express the opinion that final development or maturation of the female uterus does not depend on semen absorption, but further point out that, even if testosterone is of importance in this process, then the female already has an adequate supply of her own, for androsterone is normally excreted from the female in amounts comparable to that found in the urine of the male.

If further work on these lines confirms the negative findings of Bacsick we are left without any conclusive evidence in favour of the not very likely supposition that semen deposited in the vagina has any endocrine function, or that it has any special effect, other than fertilization, on the female organism. This, however, does not exclude the possibility that contraception may affect female fertility adversely by some other mechanism. Some methods, such as intra-uterine appliances or powerful chemicals which involve a real risk of injury and infection, are clearly dangerous from this standpoint; but what of other methods? It is alleged that even chemical pessaries of repute may lower fertility by favouring the development of cervical lesions such as erosion. It is said that coitus interruptus may disturb ovarian function, while the mere deprivation of the uterus of the fulfilment of its function by any method may increase the likelihood of fibroids and pelvic endometriosis. Some gynaecologists of wide experience, and whose opinions cannot be lightly discounted, therefore take the view that the artificial deferment of pregnancy may, by one means or another, lead to relative infertility. There has been little attempt to substantiate these clinical impressions by controlled observation—indeed, it would be difficult to do so. Siegler,⁶ however, in his recent book reports that in a study of 1,262 cases of pregnancy he found an average of two months' infertility for every year of contraception practised beforehand. However, such findings are open to several interpretations, and Dickinson and Morris⁷ in a sixteen-year study of cases of infertile marriage could find no evidence of sterility's being induced by

contraceptive methods other than those involving intra-uterine appliances. Hamblen⁸ probably states the general view when he says, "There is little likelihood that contraceptive measures of the kind generally employed at present have any tendency to impair the potential fertility of couples." At least there seems as yet no reliable evidence to the contrary.

WHAT IS GASTRIC FLU?

A diagnosis of gastric flu, or intestinal gripe as the Americans call it, is to-day made more often by the layman than by the medical practitioner. Medical men are far less prone to diagnose "gastric flu" now that they are increasingly aware of the part played by the Sonne dysentery bacillus, bacterial food-poisoning due to the *Salmonella* group of organisms, and the enterotoxigenic staphylococci in the causation of endemic or epidemic diarrhoea. Improvements in laboratory technique have enabled a bacteriological diagnosis to be made in a very high proportion of these bacterial infections even after the acute attack is over, since convalescent carriers are common after both dysentery and *Salmonella* food-poisoning. When, therefore, the bacteriologist fails to recover an identifiable pathogen from a patient with acute diarrhoea the clinician is puzzled and the diagnosis is in doubt.

There have been many instances of this kind in the past few years, and it is obvious that a non-bacterial contagious illness, characterized by profuse watery diarrhoea, sometimes associated with nausea and vomiting, or with these last two symptoms predominating, has become prevalent in certain areas in this country. Outbreaks of this non-bacterial diarrhoea, which in the individual is usually so short-lived as not to call for medical aid, are most likely to be detected in hospitals or residential institutions. Since 1936 several outbreaks of nausea and vomiting have been reported from boys' and girls' boarding schools. The characteristic features, as described by Bradley,⁹ were the sudden onset of projectile vomiting, sometimes in the middle of the night, sometimes at the dining-table, and sometimes preceded by nausea resembling seasickness. In these outbreaks diarrhoea was not a prominent feature; vertigo and headache might be present, but generalized aching was rare; chills were infrequent and low-grade pyrexia (around 100° F.) was the rule; lassitude and irritability suggestive of central nervous system involvement were not uncommon. Respiratory symptoms were not a frequent complaint, and when present were probably coincidental, but hyperaemia of the tongue papillae was a noteworthy feature in Bradley's cases, and injection of the fauces and pharynx was sometimes present. Abdominal discomfort and tenderness which may result in a diagnosis of acute appendicitis have been noted.

More recently, diarrhoea has been the prominent symptom in this syndrome, as typified by an outbreak in a maternity unit described in our columns last year by Brown, Crawford, and Stent.¹⁰ Both mothers and babies were affected, although in the babies the infection was much less severe than is the case with epidemic diarrhoea of the newborn. Diarrhoea characterized by profuse watery stools without blood or mucus was usually the first and most constant feature, although nausea and anorexia were present in most of the adult patients. The persistence of the infection in maternity units is probably related to the rapid turnover of patients. A very similar condition apparently common in America has been described by Reimann and

his colleagues.¹¹ According to them the disease attacks people at all ages, but is most common in school-children and young adults. It may occur at any season, but especially in the autumn, and it may affect 15 to 100% of the community. In its rapid and easy spread in families and in institutions it resembles the behaviour of the common cold or influenza, and Reimann¹² has been able to reproduce the infection among more than half of 53 student volunteers who inhaled atomized throat garglings or faecal filtrates from acute cases. Thus the experimental evidence supports epidemiological data suggesting that the infection may be air-borne, although obviously manual or other means of spread cannot be excluded. Control of the infection in hospitals or other institutions is not easy. Avoidance of overcrowding or temporary closure of maternity units is virtually impossible at the present time, when there is a spate of new babies and a shortage of hospital beds. But good ventilation and the strictest precautions against the risk of manual transference should be practised. Treatment is symptomatic: abdominal pain and discomfort can best be relieved by the local application of heat, together with rest and limitation of diet. Phenobarbitone or tinct. camph. co. may be prescribed for the intestinal upset.

Virus infections of the intestinal tract have in the past been regarded as rare or non-existent, but the demonstration of the aetiological agents of poliomyelitis and infective hepatitis in the stools of affected patients suggests that the intestine is no more immune than other tissues to attack by viruses. Whether this particular entity is primarily an infection of the intestine or, as has been suggested, of the central nervous system can be determined only by further experimental work.

CHORIONIC GONADOTROPHIN

The hormone present in pregnancy urine has been known for many years. Its biological actions have been interminably investigated, and it has been used extensively in clinical and veterinary treatment, yet no one has succeeded in explaining its function in human pregnancy. Hisaw¹³ has recently investigated this problem in macaque monkeys: their sex cycles are similar to those in women, and they excrete chorionic gonadotrophin. He first demonstrated a hitherto unnoticed action of the hormone. Taking monkeys in the luteal phase of their cycle, and making sure by laparotomy that an active corpus luteum was present, he then gave daily injections of chorionic gonadotrophin. The onset of menstruation was delayed in every case, the average length of the cycle being 42 days instead of the normal 27. When menstruation did occur it took place from a progestational endometrium, showing that corpus luteum function had been maintained. Corpora lutea produced by gonadotrophin injections were also kept in functional activity by chorionic gonadotrophin for as long as naturally occurring corpora lutea. Hisaw has thus demonstrated that chorionic gonadotrophin has a luteotrophic action, and this action is different from, or at all events more prolonged than, that produced by pituitary luteotrophin (prolactin). This last hormone given in high doses under similar conditions did not delay the onset of menstruation.

In the corpora lutea from the injected monkeys histological changes were similar to those described by Corner¹⁴ as occurring in early pregnancy. The walls of the endometrial blood vessels, too, were in some cases hypertrophied

(epithelioid cytomorphosis), as in the maternal vessels of the monkey's placenta. The condition of the sex skin and vagina during the injection period resembled that provoked by combined oestrogen and progesterone treatment in spayed monkeys.

On the basis of these experimental findings the author speculates on the normal role of chorionic gonadotrophin in the monkey. He suggests that the corpus luteum is maintained in a secreting condition until the time of normal menstruation by pituitary luteotrophin (prolactin). When fertilization and implantation occur the trophoblast is already developing by the time menstruation should ensue, but its onset is prevented by the secreted chorionic gonadotrophin, which maintains the functional corpus luteum for a further 10 to 15 days. When menstruation takes place during injections of chorionic gonadotrophin the corpus luteum is undergoing morphological changes which are similar to the characteristic changes seen in normal pregnant monkeys at the same time after ovulation.¹⁴ Hisaw therefore suggests that the bleeding in the injected animals is caused by progesterone withdrawal, and does not occur in normal pregnancy, because the placenta is then functional and takes over the ovarian function of secretion of progesterone.

Hartman^{15 16} has demonstrated that ovariectomy in monkeys will not interfere with pregnancy if carried out later than 25 days after ovulation. Oestrogen secretion by the monkey placenta has been reported,¹⁷ but progesterone secretion has still to be proved. Nevertheless the hypothesis is certainly consistent with most of the facts.

THE STARVED BUT NOT CORRUPT KIDNEY

Since the days of Clifford Allbutt benign hypertension has been recognized as a disease which ultimately kills by a vascular catastrophe in the heart or brain, without causing attrition of renal function of any clinical significance. In its benign evolution the disease is associated with a premature ageing and hardening of arteries and arterioles which differs structurally from the arteriosclerosis of non-hypertensives only in severity and distribution.¹⁸ In benign hypertension there is a more severe sclerosis of the renal arteries; but in spite of this greater impact of premature age on the kidneys the natural history of the disease tells us that they usually stay the course. There is abundant clinical and pathological justification for applying Allbutt's classical description of the senile arteriosclerotic kidney to the prematurely aged kidney of benign hypertension—"a starved but not a corrupt kidney sufficient for the smaller life of an elderly man." Yet renal function in benign hypertension might be adequate for normal needs but show some diminution when assessed by sufficiently delicate or selective tests. Murray McGeorge¹⁹ applied such a test, primarily in quest of prognostic data, and observed the capacity of the kidneys to concentrate simultaneously urea and chloride²⁰ in benign hypertension and in a suitable group of non-hypertensive controls. Although there was no evidence that the test was of prognostic value, McGeorge's observations of the effect of age on renal function are interesting and conform with the pathological concept of the disease. The test was sufficiently delicate

or selective to show a progressive impairment of renal function with increasing age—an impairment which was much greater in benign hypertension but perceptible even in the non-hypertensive controls. Young subjects, whether hypertensive or not, started without significant difference in renal function. When the pathological picture is considered, it seems probable that assessment of other bodily functions would show a similar steeper decline in benign hypertension if sufficiently delicate tests were available. Normal age has its gentler downward slope, but in benign hypertension "some are too early old, and before the date of years."²¹ In turning to the laboratory for renal function tests it is well to be reminded that the best test of renal function is that the kidneys continue to function.

CONVULSIONS FOR DEPRESSION

In the annual report of the Cassel Hospital,* Andratschke and Rogerson have described their findings with the electrical convulsive treatment of mild depressive psychoses. The report is interesting because of the comparison it provides between treated and untreated patients. The control group was taken from the years 1938-9, before this method of treatment was in use. The patients then had to be more strictly selected for a favourable prognosis, and with them the better results should have been obtained. Nevertheless results were substantially and significantly better in the group given convulsion therapy. The authors conclude that the position has now been reached when convulsion therapy is the treatment of choice, and definite contraindications must be present before its use is decided against. Complications are rare and not very serious; and the convulsion treatment of out-patients is justified if there are facilities for admission to hospital if required. The patients who did not respond to electro-convulsive therapy provide an interesting clinical study. In half of them treatment had to be abandoned prematurely or the patients passed out of observation before the final result could be observed. Of the remaining nine patients, three had serious psychopathic features such as alcoholism or homosexuality, three had schizoid traits and two actually became schizophrenic, and three were typical cases of recurrent manic-depression. Electro-convulsive therapy in the neuroses was not so satisfactory. Only patients with anxiety states did well; obsessional and hysterical cases did not respond. The authors believe, however, that electro-convulsive therapy can be useful in the treatment of anxiety neurosis, at least in selected patients.

The following members of the medical profession were recommended by the Council of the Royal Society for election to its Fellowship at the annual meeting on March 21: G. L. Brown, M.B., M.Sc., of the scientific staff of the Medical Research Council; G. R. Cameron, D.Sc., F.R.C.P., professor of morbid anatomy at University College Hospital Medical School; Brig. J. A. Sinton, V.C., M.B., consultant malariologist to the War Office; J. W. Trevan, M.B., F.R.C.P., director of the Wellcome Physiological Laboratories; and F. M. R. Walshe, M.D., F.R.C.P., physician to the National Hospital, Queen Square, and physician in charge of the neurological department, University College Hospital.

FREE AMBULANCES TO LONDON VOLUNTARY HOSPITALS

The London Ambulance Service has hitherto provided on a pay basis for the removal of patients to voluntary hospitals. On and after April 1 next no charge will be made by the London County Council to either patient or hospital for patients removed from an address in the County of London to a voluntary hospital in the county, except for those admitted to pay wards in which cases the existing charges will continue. For the present the service will not be available without charge for (i) discharges in need of an ambulance on medical grounds, (ii) out patients receiving treatment (iii) removals to or from places outside the County of London. Applications for the use of a free ambulance will be accepted by the headquarters of the London Ambulance Service (Waterloo 3311) only from the voluntary hospitals in the County of London or the Emergency Bed Service. Medical practitioners should not make direct application to the London Ambulance Service but in order to be sure that a bed has been definitely obtained they should make arrangements for the patient's admission with either the voluntary hospital concerned or the Emergency Bed Service (Clerkenwell 6571, City 2162). An ambulance attendant will always accompany the driver when recumbent patients are to be removed, if a nurse is required to travel with the patient she will be provided by the hospital. With non recumbent patients the ambulance driver only will be sent, and in the case of a female patient arrangements should be made for a relative or friend to accompany her unless a nurse is required, in which case she will be provided by the hospital.

FILING AND INDEXING OF UNPUBLISHED MATERIAL

Research and information departments of scientific institutions in editorial offices in public health organizations and in medical libraries extremely important information is often contained in technical memoranda newspaper cuttings, catalogues, and correspondence. Not infrequently is it essential to find a document at a moment's notice and its contents must therefore be indexed in such a way that the information is immediately available.

A well attended and stimulating conference in London organized by ASLIB (Association of Special Libraries and Information Bureaux) on Feb 15 at Friends' House Euston Road under the chairmanship of Capt H Ward, MSc, secretary of the Industrial Management Research Association, was devoted to a discussion of problems of filing and indexing unpublished material. Miss M Shaw said that in the laboratories of J Lyons & Co, Ltd, the correspondence section was thought to be as much a part of the information service as the library and was under the supervision of the librarian. Dr J E Holmstrom (ICI Ltd Central Registry) defined filing as a branch of documentation more akin to librarianship than to other office work, though it differed from normal librarianship because a file was not, like a book, a completed unit of knowledge which already had a title and whose scope could be ascertained by inspection. The filing of current papers involved deciding where to fit them into place in a pattern which had not yet taken shape. The speaker suggested a special course in business filing as distinct from ordinary librarianship, expressing the hope that ASLIB might promote such a scheme.

The discussion would have been even more valuable for a quantitative interpretation of statement and suggestions. Every organization has its own peculiar problems and difficulties, numerical and geographical, and no one system will suit everybody. An elaborate system may be evolved which enables a given document (asked for, perhaps, once a month) to be found in three instead of thirty minutes, thirty minutes a day being spent by a highly skilled, well paid staff in putting the system into execution. It was generally agreed that filing and indexing was a skilled job, and yet the registry was the last department where any employee wanted to go. Filing clerks were difficult to obtain, being poorly paid. The question of nomenclature was all important, and it was a matter for regret

that there was no popular equivalent in the English language for the French *archiviste*. Index cards (authors and subjects), extracting the maximum information from documents in the files, were valuable for giving a story at a glance without having to go to the file for its reconstruction.

Other speakers in the discussion dealt with a variety of technical problems such as size and arrangement of files, tags storage, and headings for correspondence. It is understood that the papers and the discussion will be published by ASLIB and librarians, hospital administrators, information officers, and editors will no doubt look forward to this report with interest. It is particularly hoped that some of the ideas expressed at this conference will bear fruit in large medical libraries, which have a dynamic function to perform in bringing unpublished material to the attention of interested people.

EMPLOYMENT OF THE DEAF

The Disabled Persons (Employment) Act applies to the deaf as well as to other disabled persons, and vocational training adapted to the needs of the deaf is being extended. The National Institute for the Deaf (105 Gower Street W.C.1) in its last annual report, states that it has been informed that the option of registration rests entirely with the deaf person, but the deaf person, unless registered, cannot count towards the quota of his employer. In the case of school leavers the certificate of a special school is sufficient evidence of deafness, and in the case of adults a certificate from a recognized association for the deaf would in general be accepted. Cases of doubt as to whether the deafness constituted a handicap to employment would be referred to a district advisory committee, but the final decision would rest with the Minister. The Institute suggests that welfare workers for the deaf should advise all deaf persons to register as disabled persons at the first opportunity.

In a recent International Labour Office publication dealing, among other things, with services for the deaf in Great Britain it is stated that the principal obstacle to the employment of the deaf is social prejudice, but that on the whole, the public are becoming more open minded about the employment of deaf and hard-of-hearing persons and the success which most experiments have achieved and the knowledge acquired thereby will probably help to overcome remaining prejudices.

EDUCATION FOR FAMILY LIFE

There is widespread concern to-day about present population trends, the increase in marriage breakdown rate and juvenile delinquency. These problems are symptoms of something much deeper, and a merely negative attitude is unlikely to be effective in solving them. The family was under constant attack during the war and at least for a generation before. Not the least enemy of the family is ignorance. One of the most effective means of counter attack is education.

The British Social Hygiene Council, in collaboration with the Association for Education in Citizenship and the Marriage Guidance Council, is organizing a week-end school, the first of its kind to be held in the country, to take place in Morley College, 61, Westminster Bridge Road, London, S.E.1, from Saturday, April 27, to Tuesday, April 30. It is designed primarily to meet the needs of teachers and youth leaders, parents, social workers, and others interested will be welcome. The following will speak: Mr Cyril Bibby, Dr McAlister Brew, Mrs E Hubback, Dr Housden, Dr David Mace, Mrs Mace, Mr R Weatherall, Dr Taylor (Governor of Holloway Prison). The inclusive fee is 10s. Application for tickets should be made to the British Social Hygiene Council, Tavistock House North, Tavistock Square, London, W.C.1, whence further details can be obtained.

FUTURE OF NORTHERN IRELAND HOSPITALS

Northern Ireland had a visit recently from members of the Nuffield Provincial Hospitals Trust. They went on the invitation of the Northern Ireland Regional Hospitals Council on the occasion of a meeting of the Council at which the reports of a co-ordination committee and fourteen subcommittees on hospital planning for the region were presented.

The visitors were Sir Ernest Rock Carling, F.R.C.S., chairman of the Medical Advisory Committee of the Trust, Sir George Martin, chairman of the Yorkshire Regional Council, Mr L. Farrer Brown, secretary to the Trust, and Mr C. M. Abbott, assistant secretary.

On the afternoon of their arrival they paid a visit to the Royal Victoria Hospital, the premier voluntary hospital in the region. They were, perhaps, most interested in the extensive development plans which that hospital has well under way. The following morning a visit was paid to the Newtownards District Hospital, a converted Poor Law hospital, and the Bangor Hospital, a small but first-class country hospital, run, in the main, by the local general practitioners.

The meeting of the Council was held in the afternoon, but before that the visitors were the guests of the Northern Ireland Minister of Health to luncheon. In the evening a dinner was given by the Council, at which the principal guests, in addition to the representatives of the Trust, were the Prime Minister of Northern Ireland and the Minister of Health for Northern Ireland.

Dr. D. Lindsay Keir, Vice-Chancellor of Queen's University, Belfast, is chairman of the Northern Ireland Regional Hospitals Council, and the reports presented at the meeting of the Council make far-reaching proposals for the future of all hospitals in the region.

Reports of Societies

PENICILLIN IN OTITIC MENINGITIS

At a meeting of the Section of Otology of the Royal Society of Medicine on March 1, with Mr. A. J. M. WRIGHT in the chair, a discussion took place on "Penicillin in Otitic Meningitis."

Dr. HONOR SMITH presented a paper giving the experiences of the Oxford neurosurgical unit. It related to 37 cases; in 21 the source of infection was otitis, 9 followed a sinusitis, and 7 a fracture through a sinus. In 25 of the cases the organism was the pneumococcus, in 9 the streptococcus, and the others were influenza or mixed infections. Intrathecal penicillin was used (2,000 units per ml.) in doses of 8,000 to 16,000 units. This was supplemented by the oral administration of sulphadiazine. Systemic penicillin was also given. There was no evidence that systemic penicillin could cure the meningitis: its chief value lay in the control of the primary focus. Intrathecal administration was continued for at least five days from fear of relapse, and in fact 9 of the 37 cases had one or more relapses before final recovery, while yet another patient died in relapse. Penicillin being available, emergency mastoidectomy was no longer necessary for the treatment of otitic meningitis. Both the meningitis and the primary focus could be controlled by penicillin, and if operation was ultimately necessary it could be performed during convalescence. Nevertheless, in those cases in which relapse followed relapse, the idea of an active primary focus constantly re-infecting the meninges and available to surgery made surgery appear very desirable. In the 37 cases there had been 26 recoveries and 11 deaths. Of the otogenic cases 15 recovered and 1 died; of those secondary to sinusitis 6 recovered and 3 died; and of those following fracture 5 recovered and 2 died. She stressed the importance of the diagnosis of brain abscess associated with meningitis. The clinical picture might be dominated by the finding of meningitis and abscess might not be suspected. A complicating abscess was the cause of death in 6 of these cases.

Mr. J. ERIC PATERSON offered some observations based on 6 otological cases treated with penicillin at the Glasgow neurosurgical unit. Two patients died, both of them late cases; the four recoveries had been in early cases. In pre-penicillin days, as well as after penicillin became available, a course of sulphadiazine was given. Penicillin was administered intrathecally, in doses of not more than 40,000 units; sometimes it caused a mild rise of temperature. Intraventricular penicillin was given when there were signs of a block in the cerebrospinal circulation. Systemic penicillin was a most important part of the treatment. His difficulty was to know how long to continue it. He felt that any operation on the ear should not be carried out at the height of the meningitis, and undoubtedly in systemic penicillin they had a potent weapon for controlling further spread from the primary focus to the meninges.

Mr. R. G. MACBETH said that one thing which emerged from the experience of the Oxford workers was that the mastoid

operation need no longer be a matter of great urgency. It could safely be delayed until the meningitis was under control. In the acute cases an operation need not be done other than the simple one necessitated by drainage. Penicillin did not sterilize pus inside an abscess cavity, and it seemed that myringotomy provided the necessary drainage, except in the case of an extradural abscess.

Acute Inflammation and Chronic Disease

Mr. T. B. LAYTON said that no distinction had been made in the paper presented by Dr. Honor Smith between chronic ear disease and acute inflammations of the middle-ear cleft. In every paper dealing with an otological subject that distinction should be made. It was as wrong clinically, scientifically, and therapeutically not to make it as it would be to lump together tuberculous peritonitis and the peritonitis resulting from acute appendicitis. Dr. Honor Smith was quite wrong in saying that cerebral abscess was common in streptococcal disease of the ear. It might be common in the very limited type of case with which she and Prof. Cairns had been dealing. He disagreed also with Mr. Paterson when he said that it might become necessary to operate on the acute ear, but that operation had still to be done on the chronic ear. He had made the planned experiment of refraining from operating in meningitis due to an acute ear because he thought the condition of the heart forbade a general anaesthetic. The patient came out of the meningitis, but collapsed; they then operated, and the patient died. It was a grave responsibility to refrain from removing the factory of organisms threatening the dura mater, and that was the essential thing in acute mastoid operation. He said again that papers should not be brought before them as otologists unless a distinction was made between two diseases which were different clinically, bacteriologically, and therapeutically. One was a disease of bone, contiguous to the dura mater, so that the spread from the one to the other was easy and rapid; the other was an inflammation of a mucous membrane separated from the cranial cavity by two layers of periosteum and an intervening piece of bone, and all one could do was to drain that cavity.

Mr. E. MUSGRAVE WOODMAN said that they had all been told that the primary focus should be removed when consequential complications arose, and that had been their guiding point. But they had to remember that these people were very ill, the margin of safety was low. He was rather inclined to agree that in the best interests of the patient they should think again as otologists, and it might be that the question they should set themselves to consider was whether a simple drainage without eradication should be carried out.

General Discussion

Mr. C. P. WILSON said that the type of case attending neurosurgical unit was rather different from the type which, begin with, would come under the otologist. He had an analysis of 8 cases of otitic meningitis, not one of which had a cerebral abscess; probably cases which developed symptoms associated with cerebral abscess were more likely to go to a neurologist unit. In these 8 cases he had had only 1 death—a pneumococcal case; 3 cases had shown the haemolytic streptococcus and all had recovered. He had queried the amount of penicillin used intrathecally—as much as 50,000 units—in otitic and not otitic cases, because he had felt it was likely to produce a local reaction with fibrous exudate, but the pathologist's opinion was that these cases often had a fibrous exudate without penicillin and the patients lived. Only two complications arose in the series—one a paralysis of the bladder which recovered, and the other some symptoms of *petit mal*.

Mr. L. GRAHAM BROWN said that the otologist had a little difficulty in carrying out all the complicated tests and treatments which the neurosurgeon was now making his own. He asked whether Prof. Hugh Cairns would not agree that in the cases in which brain abscess or an intracranial complication was suspected the neurosurgeon should take charge. He asked whether there was any likelihood of systemic penicillin being made a substitute for intrathecal medication. These constant lumbar punctures were a source of trouble and possibly a danger.

Mr. F. W. WATKYN-THOMAS asked whether there was any evidence that penicillin, unless administered by the intraventricular route, could actually enter the brain substance. He added that he was not quite convinced by Dr. Honor Smith's paper, and he did not think he was going to abandon the removal of a focus when there was one. Mr. H. V. FOSTER mentioned cases of otogenic meningitis which had recovered after intrathecal and systemic penicillin. In the old days one did not expect meningitis following acute otitis media to recover. The PRESIDENT summed up the discussion by saying that evidently penicillin held out the hope of helping cases which were hopeless in the past. The need for co-operation between otologists and neurosurgical units had also been demonstrated, and they were all grateful to Oxford for setting such an outstanding example.

The Neurosurgeon and Otolaryngology

Prof. HUGH CAIRNS, who replied to the discussion, said that neurosurgeons had been drawn closer to the otologists over the use of penicillin than ever before. At the risk of being tiresome he wanted to say something about the dosage of intrathecal penicillin. In the neurosurgical unit they were very much against overdosage. They thought that the standard dose intrathecally should be about 10,000 units. This might be given twice a day in the very acute phase of meningitis, but for most of the time it was sufficient to give it once a day. Excessive doses would cause trouble, such as fits, retention of urine, and other signs of damage. Furthermore, all the evidence went to show that excessive dosage was unnecessary. With the dosage recommended a concentration of penicillin in the cerebrospinal fluid would be obtained which was more than ample to destroy any of the ordinary pathogenic bacteria. Intrathecal treatment must be systematic. It was no use saying, "We will give penicillin to-day, and if the patient is a little better to-morrow we will withhold it." The shortest time for intrathecal treatment in a proved case of pathogenic meningitis was five days, and often it was desirable to go on for rather longer.

What penicillin could do prophylactically, both for infection in the mastoid and in the brain, had yet to be proved. Nobody knew whether penicillin could diffuse into the brain from the capillaries, and it was an extremely difficult problem to work at experimentally. He did not think there was any likelihood, with the present compounds, that systemic treatment would replace intrathecal.

Mr. Layton had spoken impressively about the need for distinguishing between the acute and the chronic cases, but if he would read Dr. Honor Smith's paper he would find that a distinction had in fact been made. Prof. Cairns thought that a chronic focus, where there was a collection of pus, ought to be dealt with surgically, but he was not clear whether Mr. Layton would hold his hand in any case or would just go ahead and operate on all the cases as in the old days.

The theory of immunology so far as the cerebrospinal fluid was concerned did not seem to work. Patients who got an attack of pneumococcal meningitis did not become more immune, at any rate for a long time. They might have eight or nine further attacks, though if the clinician had patience and each attack of meningitis was treated as energetically as the first, the patient would probably in the end develop some degree of immunity. Prof. Cairns concluded by saying that there was a great field for the otologist in working out precisely the degree to which penicillin would help him in the prophylaxis and cure of mastoid infection.

GYNAECOLOGICAL CASES

At a meeting of the North of England Obstetrical and Gynaecological Society held at Liverpool on March 1, Mr. J. E. STACEY, of Sheffield, described prolapse of the urethral mucosa in two sisters, aged 75 and 73 respectively. The prolapse presented as a dark plum-coloured gangrenous mass about the size of a cherry, giving rise to dysuria in one of the patients and some bleeding in the other. The protrusions were removed by diathermy and each patient made an uneventful recovery. In another case a blue firm mass about the size of a cherry which presented through the urethral orifice after a bout of pain and vesical tenesmus was found at operation to be a con-

genital pouch of the bladder wall. The mass reduced itself spontaneously as soon as the bladder was distended with fluid, and was easily ligatured and removed through the dilated urethra. The fourth case was that of a woman aged 43 in whom a smooth purple piece of tissue about the size of a Victoria plum was found protruding through the urinary meatus. As she had had amenorrhoea for three months her doctor thought that this mass must be a portion of placenta following an incomplete abortion and attempted to pull it away digitally. He (Mr. Stacey), after dilating the urethra still more, found that the mass was attached to the right side of the bladder in the region of the right ureteric orifice. It was tied off and cut by the sense of touch, and on removal was found to be a papilloma of the bladder, which had undergone torsion at its base, and a portion of the right ureter. The patient made an uneventful recovery, and on cystoscopic examination a few days later both ureters were seen to be secreting well, though the right ureteric orifice was about 1 cm. in diameter.

Dr. DUDLEY RACKER, of Manchester described a case in a young girl serving in the A.T.S. of an obturator hernia containing a portion of the right Fallopian tube and the distal part of the appendix. It caused a great deal of pain in the right iliac fossa with nausea and pain down the leg. The case had been diagnosed and investigated as one of gonorrhoea with a possible spread of the infection into the Fallopian tubes. Dr. Racker said that vaginal examination revealed a mass in the region of the obturator foramen. At operation the ovary was found to be lying close to the opening of the hernial sac, and both the appendix and the right Fallopian tube were removed.

Prof. T. N. A. JEFFCOATE showed an unusual specimen of an extracervical squamous epithelioma, and Dr. HERD one of a placental chorio-angioma. Dr. R. NEWTON described a case of post-menopausal haemorrhage due to a minute granulosa-cell tumour in the ovary which had caused endometrial hyperplasia and a small endometrial polypus.

A meeting of the Chelsea Clinical Society was held at the South Kensington Hotel on Feb. 26 under the presidency of Dr. Desmond MacManus. After dinner Dr. F. Murgatroyd, F.R.C.P., delivered a lecture on "The War and Tropical Medicine" and gave a most interesting discourse upon the difficulties and the recent advances in methods of combating tropical diseases under wartime conditions, and explained how their occurrence might be likely to affect general medical practice in Great Britain.

HEALTH EDUCATION IN SCOTLAND

At the annual meeting of the Scottish Council for Health Education held in Edinburgh Mr. Andrew H. A. Murray was appointed chairman for the ensuing year, and in moving the adoption of the accounts for 1945 he, as treasurer, drew attention to the need, imperative and urgent, for an increase in funds. The retiring chairman, Bailie Violet Robertson, LL.D., who presided, said that in a very short period the council, with the whole-hearted co-operation of the local authorities, had made its name and aims known not only in the populous urban areas but in the small burghs and many of the remotest hamlets and villages of the Scottish coasts, the Highlands and Borders. She introduced the newly appointed part-time medical adviser, Dr. Alex. G. Mearns, senior lecturer and examiner in hygiene, Glasgow University.

Dr. Mearns said that one of the council's aims should be to encourage both the universities and the teachers' training colleges to take their full share in inculcating the principles of health education. The students thus taught would in due course become doctors, teachers, etc., and would be better equipped to face the difficult task of reversing the usual conception that "the customer is always right." In many health matters the "customers," he thought, were often wrong. The public must not, however, feel that they were being dictated to. Health propaganda must be persuasive, and, at the same time, it must be truthful and fearless if lasting good was to be achieved.

It was announced that three summer schools would be held this year, two at St. Andrews University (June 29 to July 12 and Aug. 3 to 17) and one in Edinburgh (July 13 to 27). Dr. W. G. Clark, M.O.H. for the City of Edinburgh, said that a health week would be held in Edinburgh and Leith during the period April 28 to May 5 under, it was expected, the joint auspices of the council and the corporation. It would be, he said, an intensive effort to reach every family in the city, and he hoped a pattern and standard would be established by the capital which would inspire the other large burghs to follow suit and "go one better if they can."

Correspondence

India and Birth Control

SIR,—With probably the most devastating famine in history overshadowing India, Sir John Megaw's lecture on the health of India which you printed on March 9 is naturally of considerable interest and importance. The lecturer has the advantage of ample experience, and no one here or in India will doubt his sincerity of purpose and his humanity. The fact emerges, however, that the only remedy proposed—limitation of births—appears at the present juncture to be such a counsel of despair that you will, I trust, allow me to make certain observations on other aspects of this problem—namely, that of population.

In general, none will dispute the existence of certain laws of the increase of population, or the occasional association of such increase with a lowering of the level of nutrition. In actual practice there are so many extraneous factors involved that the consequences of such laws do not work out in the simple manner indicated, and indeed cannot be considered universally valid. There was, for example, a phenomenal increase in the population of Britain in the latter half of the nineteenth century accompanied by a marked reduction in the area under agriculture, due to the diversion of population to industries. There was no food shortage, but rather an increase in the wealth of the country, as the surplus food needed was of course imported, in exchange for manufactured products—as it is to this day. And yet to-day's "austerity" is such, and the man-power problem is so acute, that many have grave doubts as to the wisdom of universal birth control, and inquiries are already afoot to modify this state of affairs. How much stronger in the world the position of this country would be if the population were larger by 10 millions.

The increase of population in any country cannot now be considered as an isolated, domestic phenomenon having no relation to the outside world. There is so much exchange of raw materials, of consumer goods, and even of food between different countries that the problem cannot possibly be reduced anywhere to the classic simplicity implied by the able lecturer. Let us remember that although the Indians live in the modern world their agriculture is at present entirely prehistoric and inadequate as to the methods. Further, by improved irrigation the area under cultivation could be very substantially increased. The "outlook on life" of which Sir John Megaw complains could be changed, for better or for worse, only by a rapid industrialization of agriculture (and everything else), and not by means of wireless talks on birth control to village folk. Indeed, I doubt if any Government in power in India would be prepared to risk its neck by broadcasting such topics; and, in fact, they are not broadcast in any European countries. No European countries have so far adopted birth control as State policy, but the reverse is true of many States where it is or has been officially discouraged—e.g., France, Germany, U.S.A., U.S.S.R. Indian trade with neighbouring countries is likely to increase, and there is no reason whatever to think that it will not be to the benefit of India in the matter of food.

Our life on earth is so arranged that malnutrition and famine are not the only dangers which populations have on occasion to face. If diseases and epidemics could be controlled (and some endemic infections do not spare the well-nourished) there would still be war, involving much loss of life among the younger age groups, and subsequent economic distress and famine, extending to all sections of populations over wide areas. The present food situation in Europe is there for all to see, but obviously cannot be explained by population theories. The atomic bomb promises to destroy large numbers in all age groups in the next war.

I fear that politics cannot be left out of population problems either. It is no secret that nations have built up their prosperity, not by reducing their numbers, but by providing for their increased needs by foreign trade and colonization. There is the "white Australia" policy, which condemns a continent two and a half times the size of India to be cultivated by a population no larger than that of London. There are similar considerations in East and South Africa, where nevertheless

Indians have helped substantially in the economic development of the country, have benefited thereby, and have as a consequence aroused jealousy. There are vast spaces waiting to be utilized, distances are becoming smaller, and the energy and resources available to science are already immense. One cannot do better than repeat the quotation used by Mr. Churchill in his famous recent speech in America: "There is enough for all. The earth is a generous mother. She will provide plentiful abundance food for all her children if they will but cultivate her soil in justice and in peace." Incidentally, Mr. Churchill, contrary to recent trends, envisaged an increase in Britain's population to 80 millions in half a century—"spread about the world." No one can tell how and where the extra food required will be produced.

The whole subject of human fertility is as yet not perfectly understood. Considerable and intensive research in this difficult field is required before we are in possession of those factors which will enable us to decide whether or not it is possible or practicable to modify them deliberately, in positive or negative sense. From a purely clinical point of view, I doubt whether there is a doctor with long experience or a gynaecologist, who will deny that there is at least as much domestic unhappiness, frustration, and (particularly among women) general ill-health and neurosis caused by the widespread use of contraceptives as the theoretical benefits they are supposed to confer on society. I have questioned women closely, and there is no doubt that the existing contraceptive alter the nature of the sexual act very considerably, and that this apparently economic necessity is tolerated even though it is felt by refined natures to be repugnant. No organized team of medical men has yet carried out any research, inquiry, or experiment in this particular field (of practical birth control) and it is strange how everyone has become reconciled to the conceptions and commercial products of non-medical amateurs.

Finally, "birth control" is by no means a simple remedy in the medical sense—that is, with a specific and limited action: for by altering the sexual habits of the people it is bound to have repercussions on the social structure of a society, and indeed, in the long run, on moral outlook and behaviour. I am for this reason that I consider it a "counsel of despair," and it cannot lightly be recommended to India, which has its own highly developed system of ethics, and a social structure which has stood the test of centuries. It remains to be seen whether it will stand the test of adaptation to modern industry.—I am etc.,

Dagenham, Essex.

RASHEED AHMAD.

The Health of India

SIR,—The views (March 9, p. 343) of an "elder statesman" of the Indian health services like Sir John Megaw must be treated with respect, but they induce in me—a mere wartime "hanger-on"—profound pessimism. Indeed, it seems necessary to consider whether preventive medicine in India is worth while pending the arrival of the "new outlook" among the Indian population.

The Famine Inquiry Commission (Final Report) says: "A rise in the standard of living is the primary means of checking the rate of population growth." Sir John says: "It would be the height of folly to rely on a comforting theory based on no reliable evidence and flatly contradicted by experience in India." Leaving aside the question of evidence (which has been dealt with in some detail by the Famine Inquiry Commission) it is clear that, whether or not the theory be wholly true, it has the great merit of providing hope where otherwise little exists and of suggesting a course of action which is sorely needed on other counts. It also justifies the Government of India in having obtained the advice of a series of expert Commission and committees on how to increase food production and raise the standard of living. If the theory be wrong, as Sir John believes, we may as well abandon all public health activities in India until the population is induced—possibly through a formula suggested by the new Commission which Sir John proposes—to control its own reproduction rate. One wonders what line such a Commission could take. Birth-control propaganda cannot be effective unless the cost of contraception can be borne and the desire to limit families is present. Even if the question of cost were overcome, surely the desire to limit

families is dependent both on the wish to attain a higher standard of living and on there being a real possibility of doing so by individual effort. I would therefore suggest that Sir John is putting the cart before the horse when he emphasizes the need for a new outlook on the part of the Indians and relegates the 'ambitious plans' for increasing food production in India to a short and generalized statement.

To-day in India most issues reduce themselves to political terms, at least in Indian eyes. For us in Britain it is important to realize that the cause of neither material improvement nor education can be effectively fostered by democratic means until political calm is restored and the Government receives a wide measure of popular support. How this essential state of affairs is to be brought about is up to the Indian leaders and the British Government and I cannot pretend to know the best answer.

Some of these ideas have been elaborated in a paper which I gave recently to the Nutrition Society, in the *Proceedings* of which it will appear in due course. I shall not burden your columns further except to emphasize that the only hopeful (and practical) way of dealing with the question of health in India is, first, to increase food production and raise the standard of living generally, secondly, to work for the earliest possible political settlement, and, thirdly, to inculcate in Indians the desire for a new way of life. The last problem may be approached through a suitable Commission, as Sir John suggests, but failure to find an early solution to the first two (now that the preliminary fact finding is virtually complete) will certainly frustrate any attempt to bring about the new outlook in which ultimate salvation lies—I am, etc.,

Rowett Research Institute, Aberdeen

ANGUS M. THOMSON

Dosage of Diphtheria Antitoxin

SIR,—Old residents at the Edinburgh City Hospital must have noted with some surprise the statement by Dr James Grant (March 2, p. 309) that "such an authority as Ker (Banks, 1934) held that the administration of antitoxin in excess of 6,000 units was wasted." The fact is that this view was not attributed to Ker by Banks who said in his presidential address to the Fever Group on Dec. 1, 1933, "In the early post war years, when 8,000 units was suggested by the Ministry of Health as the minimum dose to be given in any case of clinical diphtheria, the late C. B. Ker vigorously protested against the waste involved in ignoring the perfectly effective dosage, in experienced hands, of 2,000 to 6,000 units for mild cases." Nor is Dr Grant's statement of Ker's views in accord with the latter's practice, which is best summed up in the 1920 edition of his *Infectious Diseases* by the following quotation: "In severe nasopharyngeal and laryngeal cases it may be necessary to give in all 40,000 units or even more. My own largest dose has never exceeded 64,000 units." In such cases the total was reached by repeated injections of 8,000 to 10,000 units given at six- to eight hourly intervals, and this system of dosage was adhered to by Ker up till the time of his death—I am, etc.,

Edinburgh

ALEX JOE

Diphtheria Immunization

SIR,—In the abridged version of Dr James Grant's address on "The Problems of Diphtheria" (March 2, p. 309) there seems to me an important discrepancy. Speaking of antitoxic immunity he remarks that this "can be set up and stimulated by injections of toxoid, which is the rationale of the immunization process, of the success of which the usual criterion is the conversion of a Schick-positive reaction to a negative." Again, "If there is basic antitoxin—i.e., if an antitoxin producing mechanism already exists—the rate of production of antitoxin will be found accelerated, and this ability to mobilize antitoxin is the best defence against clinical sequelae to infection."

So far so good. What he does not emphasize is the importance of always doing a Schick test before proclaiming "immunity." In other words there is no justification for claiming immunity unless the verdict rests on at least one negative Schick test. In passing he said that a negative test does not necessarily preclude an attack of diphtheria. What is claimed—and Bousfield, among others, has already weighty

evidence on this point—is that once a Schick-negative child, if it ever does get diphtheria, will not die of it.

This lack of precision is manifest in the table, showing 965 cases (61 deaths) among the "non immunized" and 245 (1 death) among the "fully inoculated." But what does "fully inoculated" mean if not, by antithesis and implication, "immunized"? We are told that the "death" in this series received 0.1 and 0.5 ml of A.P.T., a dosage condemned as inadequate, i.e., this patient does not really belong in this column. Moreover, all who regard the Schick test as an essential part of the process of artificial immunization know full well that certain individuals do not become Schick negative after the ordinary course. Differences in constitution, condition, technique, and material all contribute to this phenomenon. The table as it stands testifies strongly for immunization, of which Dr. Grant is himself an able exponent. But without the confirmation supplied by the test these 245 "fully inoculated" cases tell us little save that the mortality among them is negligible. On the other hand the "anti-fanatics" will doubtless once again find in this table fresh ammunition for their campaign—I am, etc.,

H. LYNDBURST DUKE

Diagnosis of Amoebiasis

SIR,—I read with great interest Surg. Lieut.-Cmdr. W. E. Kershaw's article on the diagnosis of amoebiasis (March 2, p. 305). He expresses his anxiety at the problem of amoebiasis in Europeans in the Far East with its ultimate effect on those at home. He calls it one of the major problems confronting the medical authorities in the Far East. In this connexion he does not mention one serious source of contamination likely to occur at home—ex P.O.W.s from the Far East. I most heartily welcome his remarks as giving voice to a situation that has been a constant worry to me for the last three and a half years, during which time I have been carrying on a most disheartening struggle against amoebiasis in P.O.W.s without the proper drugs or facilities. I estimate that at least 25% of all P.O.W.s who were released in August from Siam were at any rate cyst-carriers. The tests which it has been possible to carry out during repatriation, rehabilitation, and demobilization have not been, to my mind, conclusive. I found in Siam that at least nine stool examinations were required before you could be in any degree certain that the person was cyst negative, and that only if other suggestive symptoms were entirely absent. Oddly enough, in taking successive daily examinations the fifth and eighth days were most often the optimum.

Europeans from many countries at home and abroad were with me in Siam, and their views were widely different. While many agreed with me as to the danger of losing track of cyst-carriers, others were lukewarm and some went so far as to postulate that a high-percentage cyst-carrying community was not of necessity anything to worry about unduly in hygienic surroundings. In support of this they quoted figures of Manson-Bahr showing carrier rates in various communities and classes, pointing out that there are considerable numbers of cyst-carriers in the U.K. who have no symptoms and apparently never had the disease. The answer to this is that it has been neither proved nor disproved that different strains of *Entamoeba histolytica* may have different virulence. Some of the cases in Siam were of appalling severity and virulence barely hinted at in the average textbook, while others were of different grades of severity.

Introduction of numerous cyst-carriers into European communities at home especially, and also abroad, may well be fraught with eventual unfortunate results as outlined by Surg. Lieut.-Cmdr. Kershaw, and I welcome his article drawing attention to these dangers—I am, etc.,

Command Laboratory, York

L. R. S. MACFARLANE,
Lieut.-Col. P.A.M.C.

SIR,—One should not, perhaps, at such a distance, venture to criticize the findings of Surg. Lieut.-Cmdr. W. E. Kershaw, whose paper entitled "The Diagnosis of Amoebiasis" appears in the *Journal* of March 2 (p. 305) but in view of the number of cases of what appear to be bowel neurosis returning to this country from over-seas, with a history of having had amoebiasis, such criticism may not be entirely out of place.

It is true, of course, that cases of amoebiasis presenting atypically (for example, as a right-sided pleural effusion) are sometimes missed, occasionally with disastrous results, and that a sharp watch should be kept for such cases; but one of the most unsatisfactory aspects of amoebic liver infection is that there may be no history of any previous noteworthy bowel disturbance, or even any impairment of general health prior to the onset of symptoms originating from a liver abscess. Recorded amoebiasis has reached local epidemic proportions on several occasions. It occurred, I believe, in India both before and during the 1914-18 war, and occurred in Malta and in parts of the Middle East in this war. I had considerable personal experience of the occasion when, in Malta in 1942, an epidemic of amoebiasis had begun to reach alarming proportions only to die out as rapidly as it had begun, following the dissemination of some expert instruction in the art of differentiating the various protozoa which infect the human alimentary tract. It may be impertinent to suggest that the same thing has been occurring in Ceylon, but the following points might nevertheless be tentatively put forward.

1. The route and mode of infection in amoebic and bacillary (acute, subacute, and chronic) dysentery are the same, but the latter infections are very much more common, and when the incidence of amoebic dysentery exceeds 10% of the whole it is time to suspect diagnostic errors.

2. The diagnosis of amoebic dysentery is based on the finding in the stools of actively motile specimens of the *Entamoeba histolytica* containing ingested red cells. Many, some of them quite lyrical, accounts of the sigmoidoscopic appearances exist, but if ulcers are present the amoebae can be demonstrated in the stools following a saline aperient, and they can often be found when the ulceration is beyond the reach of even the most practised sigmoidoscopist. The diagnosis of caecal and of hepatic amoebiasis is made with much more difficulty on symptoms and on clinical and radiological signs, and cysts can usually be found to confirm the diagnosis. A valuable sign may be a marked increase in the number of cysts passed, following one or two doses of emetine.

3. The history of slight impairment of general health and occasional slight irregularity of bowel habit, obtained by direct questioning of people found to be passing cysts, the proportion of whom in any populace seems to vary widely with the skill and perseverance of the investigator, is not really valid evidence unless compared with the result of such questioning in those who are not passing cysts.

4. The differentiation of the vegetative and cystic forms of the various amoebae and of macrophage cells is a matter of some difficulty. Indeed, I know of no method of acquiring the ability to differentiate them with confidence except by fairly prolonged and personal "showing how" by an expert on the subject; and I recall that, whereas before receiving such instruction I thought myself fully capable of recognizing these animals, it took considerable time and much patience on the part of my instructor before I really began to know what I was doing at.—I am, etc.,

Wokingham

J. J. KEMPTON,
Late Medical Specialist, R.A.M.C.

Treatment of Amoebiasis

SIR,—Major C. F. J. Cropper (March 9, p. 366) expresses the hope that "more authoritative voices . . . will be raised in protest against the astonishingly ill-informed letter of Dr. E. Snell." I am reluctant to prolong an acrimonious correspondence, but I cannot refrain from expressing a protest that such an astonishingly discourteous letter should have appeared in your *Journal*. Apart from the fact that Dr. Snell stated that he had been a prisoner of war and, therefore, presumably not in a position to treat amoebiasis, or any other disease, by the most up-to-date methods, I am not ashamed to confess that his ill-informed views are shared by me, and, I imagine, by many other physicians experienced in tropical diseases.

It is to be hoped that the introduction of diodoquin and penicillin represents an advance in treatment, but to date experience is insufficient to justify the didactic opinions expressed by Major Cropper.—I am, etc.,

South Croydon.

T. W. PRESTON.

Ocular Signs in the Prisoner of War from the Far East

SIR,—Major G. C. Dansey-Browning's letter (Feb. 23, p. 288) brings up again the question of the aetiology of the optic atrophy that is found to be present in the ex-P.O.W.s from the Far East.

In May, 1945, I examined in a base hospital in India 33 B.O.R.s and one British officer ex-P.O.W.s who were complaining of loss of vision. These were from the first batch of 315 P.O.W.s who had been released under four weeks previously from Rangoon jail. I found loss of vision to be associated with optic atrophy in 12 of these. One case exhibited nystagmus. In none was there any ocular palsy. As these men were retained only a few days on their way to the U.K. visual field examination and scotometry were unsatisfactory. I am delighted that their subsequent examination was completed in detail in England.

In my report on these cases of that month to G.H.Q. I stated that I considered the optic atrophy to be secondary to retrobulbar neuritis caused by vitamin B₁ deficiency. But Lieut.-Col. Garland, who was my colleague, suggested, as Major Dansey-Browning has quoted, that it might be due to vitamin A deficiency. It was remarkable that, although there did not appear to be any vitamin A in these prisoners' diet, night blindness was not universal, and some of those showing well-marked atrophy had not suffered from it. The prognosis of these cases is not universally bad. I have known one civilian doctor who showed severe optic atrophy improve in vision from "barely able to read newspaper headings" to J.2 in under two months from date of release.

Although I saw no trachoma in Europeans, either in this first batch of ex-P.O.W.s or in the many that I subsequently examined, it was a serious complication in Indian troops. Many of these had attacks of active trachoma while P.O.W.s, and, in the total absence of treatment, were released with gross corneal scarring. In one, the vision was reduced to perception of light in each eye.—I am, etc.,

Palmerstown, Co. Dublin.

L. B. SOMERVILLE-LARGE.

The Cephalin Flocculation Test in Malaria

SIR,—When I published my experiences of the cephalin-cholesterol flocculation reaction as a test of hepatic function (Dick, 1945) I drew attention to the fact that this test was negative in healthy controls but positive in a small percentage (7.7) of those suffering from various disorders, not primarily hepatic, in which other liver efficiency tests revealed no disordered function. Two such patients suffered from malaria, and the reaction became negative subsequent to antimalarial therapy. I read with interest Dr. Makari's article of Feb. 23, and I should like to add that I have carried out this test in many patients suffering from malaria, and without exception it has been strongly positive in the presence of an active infection. The cephalin flocculation test is so easily carried out, but its value has not yet been generally recognized. I would agree with Dr. Makari that it is most useful as "an index of the activity of malaria parasites in the host." Care must, however, be taken in the interpretation of the test at the onset of recognizable symptoms which might be due either to malaria or to infective hepatitis in the pre-icteric stage, but the E.S.R. as shown by Wood (1945) proves helpful in such cases, as it is invariably raised in malaria but not in the early stages of infective hepatitis.

I would add that I have received from the Wilson Laboratories Ltd. in Chicago, U.S.A., a cephalin-cholesterol mixture which I have tried out and find entirely satisfactory.—I am etc.,

Inverness.

The Incision for Appendicectomy

SIR,—The controversy McBurney's *versus* Battle's incision for appendicectomy is heavily weighted with experience and tradition on both sides. Certain schools exist which hold rigidly to one incision to the exclusion of the other, and indeed of all other incisions. Is it not possible to separate cases into groups for which each incision has particular advantages?

In the first place the interim appendix and the acutely inflamed appendix lying conveniently in the right iliac fossa can obviously be conveniently removed through either incision. Both are excellent. Most of the trouble from appendicectomy, however, in my opinion, follows the removal of the difficult, adherent, acutely inflamed, and perforated appendix. If such an appendix lies in the paracolic gutter the McBurney or a muscle-cutting incision has the advantage of being immediately over the appendix, of allowing its removal from the flank without interference with the central part of the peritoneal cavity, and of allowing the insertion of a drain which is in contact with no other viscus than the caecum. A drain like this is unlikely, therefore, to cause adhesions other than between the caecum and the abdominal wall. If such an appendix lies at the brim of the pelvis it can again be removed equally well through either of the two incisions. If its site has to be drained, however, a drain through a Battle's incision must necessarily lie in contact with coils of ileum. Through McBurney's incision a drain may be placed to lie between only the caecum and the abdominal wall. Dangerous adhesions round the ileum are therefore, less likely.

Finally, if an adherent, perforated appendix lies at the bottom of the pelvis we should be able to diagnose its site before operation and to act accordingly. The McBurney incision here has little in its favour, involving extension, retraction possible injury to nerves, and trauma. Similarly a Battle's incision requires downward and inward extension, and strong retraction with possible injury to nerves, which its designer so admirably avoided. In such cases an incision through the midline or through the inner border of the right lower rectus has surely much in its favour.

I venture to suggest that it is sound teaching to make every effort to diagnose the site of the acutely inflamed appendix before operation and to vary the type of incision accordingly.—I am, etc.,

Southend General Hospital

ANDREW MONRO

Physical Therapy in Mental Disorder

SIR,—Surely the real proof of the efficacy of physical treatment will be the percentage of recoveries on all admissions to mental institutions. It is not always easy to decide whether a discharged patient should be regarded as "recovered" or "relieved," or "unrelieved" or "not improved," and the personal equations may cause considerable differences in the returns from individual hospitals, but taken *en masse* in the Board of Control reports a high degree of accuracy must be assumed. In that for 1921 the recovery rate on total direct admissions was 32.52% (males 28.08, females 36.26). In county and borough mental hospitals it was 31.82%, in registered hospitals 44.89, in licensed houses 36.32. This rate was practically the same for the decade to 1920. In the report for 1939 the rate in county and borough mental hospitals was 33.7% (males 31.4, females 35.5). The increased male recovery rate must be due, I consider to a diminution of admissions of general paralytics, as in 1920 they constituted 16.9% of the male admissions (2.9% female). By 1939 carbazol and insulin treatment had been given in many institutions and can hardly be said to have influenced the recovery rate, as shown by the female percentage. Of recent years, owing to paper economy, the reports have not been distributed, but as many cases must have been treated, at first at all events, in Service hospitals, it may be a year or two before they can be accurately compared with the earlier returns.

In assessing recovery rates for different periods various factors have to be considered. A good many years ago many cases of recent alcoholic psychoses were admitted, and these tended to increase the number of recoveries just as the many paralytics tended to lower the number. Indeed the late Sir Thomas Clouston estimated alcohol to be a causative factor in 26% of his admissions to Morningside—probably four times as much as the present rate. Further, the death rate has steadily decreased.

As regards the efficacy of convulsive therapy, naturally the question of diagnosis is important. Do those who claim success in cases of schizophrenia regard this affection as identical with Kraepelin's conception of dementia praecox, or do they label any case which they consider of the schizoid type as schizophrenia? I am sceptical of the recovery of any real dementia

praecox case by convulsive or any other therapy. Is a reasonable time given for the chance of recovery in a case of recent onset by ordinary means? In a London Command hospital for psychotic officers, during and after the 1914-18 war, I saw quite a number of cases, sent in as dementia praecox, who recovered, and usually proved to be exhaustion psychoses. The empirical nature of convulsive therapy is of course unsatisfactory. In June, 1938, Drs Rees Thomas and I. Abel Wilson, Medical Commissioners of the Board of Control, published a report on the treatment of schizophrenia by carbazol and insulin. They gave no fewer than eleven theories as to the mechanism of improvement. I will quote only the eleventh—psychological stimulus or help. A number of years ago focal sepsis was considered an important cause of mental illness, and much work was done by Birmingham alienists in regard to sinusitis, and success claimed, but their results were not confirmed by later observers. I remember being present at a discussion on focal sepsis in the Mental Section of a B.M.A. Meeting in Edinburgh, when one speaker declared the recoveries by treatment of such were just the cases that would have recovered in any case, and his remarks were applauded.

Will the same one day be said of convulsive therapy? We certainly are as yet unable to give a verdict. The many experienced alienists who give this treatment would not persist with it if they were not convinced of its value. Some consider it more useful in involution cases and in the affective psychoses than in schizophrenia. I think that in the course of a year or two a careful evaluation of the Board of Control recovery rate statistics should settle the matter. Mere figures are not sufficient. It is likely that with increased longevity and a lower birth rate the proportion of senile cases will increase. Alcoholic cases should continue to diminish. General paralysis may do so for a time, but might rise later due to war incidence of syphilis.

Another unsatisfactory feature is the lack of knowledge of the pathology of early schizophrenia and of other states. Various changes have been described in the brain and in the sex and other glands, only to be refuted later, and perhaps put down to artefact, mode of death, and so on. I think more histopathological work should be done, as in the time of Bevan Lewis, Mott, and Shaw Bolton. The last-mentioned found micrometric deficiency in depth of the layer of small pyramids.

I believe schizophrenia, and probably most cases of insanity to be due to some original inborn weakness, and in fact to be deficiency diseases, and it is not surprising the recovery rate should be one-third of the admissions. It is satisfactory it is so high.—I am, etc.,

Hastings

HARVEY BAIRD

Leucotomy in Post-encephalitic Conduct Disorder

SIR,—I have read with interest Dr F. T. Thorpe's article on prefrontal leucotomy in treatment of post-encephalitic conduct disorder (March 2, p. 312), and, by adding to Dr Thorpe's two cases a very similar case from Shenley would like to draw further attention to this arresting account of how surgery may be instrumental in modifying psychotic behaviour.

A woman aged 35 was admitted to hospital in September, 1944, as a case of post-encephalitic Parkinsonism with mental disorder. The earlier history was inadequate because of unreliable and scanty data from the relatives, and there was no record of an attack of encephalitis lethargica. At the age of 17 she attempted suicide by cutting her throat. Soon after her marriage at the age of 23 her disposition became erratic and moody and she became abnormally acquisitive.

On admission the patient showed a mask-like face, a festinant gait, and paresis of the right arm and leg with spasticity and cog wheel rigidity. Salvation was excessive. Her general attitude was simple and childish, but there was evidence of a cunning, scheming tendency towards the nursing staff. About a month after admission she began to make impulsive dashes for the window and would succeed in her attempts to break through the glass almost every week. Frequently there were scalp wounds which needed suturing, but there was never any serious head injury. Nine months after admission the patient began to complain of hallucinations—"her husband's voice" would urge her to rush to the window, and she would often give the medical staff warning when these hallucinations were most persistent. She also became deluded that there was "some thing wrong with her bowels, being preoccupied with the idea that they were "stopped up."

Prefrontal leucotomy was performed by Mr. T. G. I. James in November, 1945. An incision was made on either side, 6 cm. above the zygoma and 3 cm. behind the orbital margin. The leucotomy needle passed just anterior to the anterior horn of the lateral ventricle and 1 cm. short of the medial aspect of either cerebral hemisphere. The operation was performed under cyclopropane anaesthesia. As soon as the patient regained consciousness a marked improvement was noted. She was calmly rational and, although "the voices" were still present, there was no longer any need to pay attention to them. There were slight headache and some vomiting for a day after the operation, also incontinence of urine. One week later there was continued improvement and the hallucinations had become insignificant; on the sixth post-operative day incontinence had ceased. The patient had become interested in reading. Two weeks after the operation she was able to go for short walks in the hospital grounds, and was showing co-operation and even initiative in assisting the nursing staff in the ward. She was discharged from hospital on Jan. 13, 1946, having made no impulsive attempt to break a window during the eight weeks following the operation.

During the past two months the initial improvement has been maintained. The patient is active and mentally alert, being well able to work at home and go shopping on her own. The physical signs of Parkinsonism are less pronounced than before the operation and there is a definite gain in weight. Unfortunately the onset of double incontinence since the patient's discharge from hospital raised a temporary barrier to useful employment outside the home, but it is hoped that there will be opportunity for rehabilitation towards a more independent way of life in the not too distant future.—I am, etc.,

Shenley Hospital.

E. S. LOWER.

Fractured Patella

SIR.—Concerning the case reports quoted by Mr. R. Brooke (Feb. 16, p. 231) on his end-results of the operation of removal of the patella, although I published in the *Journal* a small series of cases soon after Mr. Brooke's original work (1938, 1, 383) extolling the virtues of this operation, I am afraid that time has modified my early optimism. I now share the more conservative outlook put forward by Sir Max Page as to when the patella should be removed.

To secure perfect function of the knee-joint after this operation needs: (1) first-class surgical repair work; (2) prolonged after-care and enthusiasm; (3) a suitable patient. I only rarely secure all these three concepts, and, judging from the cases exhibited at medical meetings, other surgeons seem to find it likewise. Even at the last British Orthopaedic Association clinical show an A.T.S. girl was shown who had her patella removed by a first-class team of surgeons together with the help of a first-class rehabilitation centre; yet in this apparently ideal case the girl could not fully extend the knee, nor had she good power in getting up from a kneeling position.

To guard against this lack of full extension, I myself, after removing the patella, endeavour to take up all slack in the quadriceps mechanism by overlapping the aponeurosis, as in the Mayo umbilical hernia operation; keep on an Esmarch bandage for a couple of days to prevent bleeding of the torn quadriceps clotting and binding it down to the capsule and lining adhesions; and I get the patient weight-bearing after a few days, guarding my suturing by providing a back slab of plaster; thus early restoration of quadriceps tone is secured. In spite of all these measures my cases of removal of the patella rarely secure more than 80% full function or power in the knee. Mr. Brooke must have some magic secret to secure his perfect results.—I am, etc.,

London, W.1.

G. O. TIPPETT.

"Eumydrin" Treatment of Vomiting in Infants

SIR,—I am prompted to write on the subject of the "eumydrin" (methyl atropine nitrate) treatment of vomiting in the young infant. Within the last two years I have been meeting an increasing number of cases in which the early use of this drug has caused considerable difficulty in making a diagnosis and prescribing treatment.

Paediatric practice is somewhat divided on the question of operation as opposed to medical treatment in pyloric stenosis of infancy, and since the general practitioner may not see sufficient cases to be able to form his own opinion his position is a difficult one. In my view both methods have a definite

place, though I believe that surgery is advisable in severe cases and should be undertaken with the least possible delay after relief of dehydration. Operation should also be performed when there is not a really good response to the drug after two or three days' trial and immediately an infant shows signs of "hanging fire" during medical treatment, so that it is not allowed to deteriorate. Furthermore, as the chief danger to the baby after operation is the infection which it may acquire even in the best of institutions, I believe that the main value of "eumydrin" lies in the fact that some of these cases may be satisfactorily nursed in their own homes. Prolonged medical treatment of these delicate infants in an institution is surely wrong unless we have the ideal conditions for admission of mother and baby and for the mother herself to undertake the nursing under supervision.

My plea is for the diagnosis to be established beyond reasonable doubt before "eumydrin" is begun. I am now meeting cases which present a very difficult problem. Typically the story is this. An infant in the first month of life has begun to vomit and the vomiting is occasionally projectile. Visible peristalsis may or may not have been seen but no tumour has been palpated. "Eumydrin" treatment has been started, and for a week the vomiting has decreased and the infant has gained a little weight. There may then have been one to two weeks of little or no progress followed by a return of vomiting, though this is no longer projectile; there has been considerable deterioration in the infant's condition and the stools may be frequent and undigested. When asked to see the baby at this stage one may find parenteral infection or faulty feeding as a cause of the condition, but one may be quite unable to decide whether pyloric stenosis is, or even has been, present. No peristalsis is to be seen and no tumour palpated. One may stop the "eumydrin" for forty-eight hours in the hope of being able to establish the diagnosis, but the infant's condition deteriorates further. As one is still uncertain one is forced either to resort to the drug again and hope to keep the infant alive with parenteral fluid, etc., or to ask the surgeon to explore in the absence of a definite diagnosis and on a bad surgical risk.

Should the family doctor be certain of the diagnosis "eumydrin" may be started and, in some cases, the whole course of treatment may be carried out safely and satisfactorily in the baby's home. There must, however, be facilities available for the immediate transfer to a surgeon if progress is arrested even for a few days, and the practitioner must be acquainted with the fact that drug treatment needs to be continued long after the cessation of symptoms. If there is the slightest doubt as to the diagnosis then the surgeon or physician who would ultimately have the responsibility of the case should personally examine it before "eumydrin" is begun, and, where possible, this first examination should be made before admission to hospital.—I am, etc.,

Oxford.

VICTORIA SMALLPEICE.

Keratoconjunctivitis

SIR,—I have been much interested in the remarks of Drs. W. J. B. Riddell and I. C. Michaelson (Jan. 5, p. 28) in connexion with my article on keratoconjunctivitis. Virus keratoconjunctivitis is, of course, a different disease from the one described in my paper.

It seems that the nomenclature of keratoconjunctivitis could be improved. I do not know if a label has ever been given to the type of case that I described, but I suggest "marginal keratoconjunctivitis," as the lesions are always close to the limbus; "keratoconjunctivitis" without a qualifying adjective is not descriptive enough.—I am, etc.,

48 General Hospital, B.T.A.

R. J. BUXTON.

"Deck Ankles"

SIR,—I cannot agree with Dr. K. Zacopoulos's conclusions (March 2, p. 322) that traveller's oedema and "deck ankles" are the same. Reference to my investigations as reported in the *Journal of the R.A.M.C.* for December, 1942 (of which the *A.M.D. Bulletin*, No. 21, para. 150, is an extract), will show that the latter is accompanied by inflammatory changes, while the former is "without further signs of inflammation."

A form of oedema in travellers by sea caused by inactivity was described in the *British Medical Journal* in 1943 (June 5, p 708) by a ship surgeon, who concluded that it was caused by sitting for long periods in deck chairs. I have discussed the aetiology of "deck ankles" with several M.O.s who had cases on troopships, and they are all agreed on the traumatic factor in this condition—I am, etc.

W. F. L. FAVA

Local Cod-liver Oil for Colds

SIR.—In the *Journal* of Feb 15, 1941 (p 262), Dr. W. Pridham-Wippell wrote of his successful use of pure cod liver oil for relief of the common cold. When I got to hear of it I was surgeon with the North Atlantic convoys and adopted his method at once, and for the past five years in many parts of the world, at sea and on shore, have continued it almost to the exclusion of all other treatment. The results have been excellent. In approximately 300 consecutive cases of which close track could be kept 7 out of every 10 treated in the first two days of symptoms cleared up entirely within twenty-four hours. Colds neglected in the early stages took longer to respond.

The method used is to have the patient lying on a couch or on the ground, no pillow, or one just under the neck, and the head well back. An average of one to two teaspoonfuls of cod liver oil is injected down each nostril, using any convenient syringe of the glycerin type, or a 10-ml glass barrel and plunger of the Record pattern. Rubber bulbs are best avoided as the oil quickly destroys rubber. The oil, partly absorbed as it passes over the turbinates, runs back over the adenoid tissue to the back of the throat, where surplus not absorbed is just swallowed. Some people are nauseated by it, but soon get over their objection when they realize the amazing relief it brings. The Service personnel soon learned to come regularly at the first sign of a cold. One application was then usually enough, but in more advanced cases two or three days' treatment twice daily might be needed, while heavy, well-established colds did not readily respond, owing probably to mucous secretion preventing the oil coming in close contact with the membranes. Care should be taken that old rancid oil is not used, as the application is then painful to the delicate tissues. I had recently to condemn many gallons of hospital stock for this reason, and found a welfare clinic issuing equally bad oil to its babies.

The rationale of the treatment would appear to be that when the turbinate mucous membrane gets unusually dry and lacking in vitality, colds readily get a hold. Cod liver oil provides essential vitamins A and D, not to do any direct germ-killing but to nourish the membrane sufficiently to allow it to do its own killing. It is often found that with a very dry mucosa the first application to each nostril is absorbed completely, as though by blotting paper, before it can reach the back of the throat.

I have extended the cod-liver-oil method to cases of sinusitis on the basis of clearing up nasal foci of infection, and results have been good in many cases. The whole body benefits amazingly from the absorption of the oil, and to a much greater degree than with the usual oral administration, cases such as bronchitis responding directly. I have applied the above treatment to myself over the past five years and have been almost trouble-free where colds are concerned, previously it was a different story.

I am glad to have the chance of reporting my own experience of Dr. Pridham-Wippell's method, as I have not so far found any other doctor, either at home or over-seas, who has used it since it was first published. I never go anywhere in my travels now without cod liver oil in my kit—I am, etc.

Dundee

HARRY R. LILLIE.

Myringotomy and Paracentesis

SIR.—May I reply to my friend Dr. T. B. Jobson's letter (Feb 23). He reprimands me for referring to myringotomy as "cutting the drum." The drum, he says, is a cavity, the tympanum. The first "ear" book I opened after reading this happened to be the *Treatment of Chronic Deafness*, by Dr. Cathcart, consulting surgeon to the Throat Hospital, Golden Square, and late member of the Special Aural Board, Ministry of Pensions. On page 8 he speaks of "the external auditory meatus, which is closed at its inner end by the tympanic membrane or drum separating it from the tympanic cavity." A number of other otological writers use the word "drum" as

synonymous with the drum head and tympanic membrane. Some of them speak of incising the drum. I will not bother you with the references.

The *Oxford Dictionary* defines the drum as a cavity, and Haultubron's *Physiology* (1923) says on page 829, "The riddle ear, or tympanum or drum, is separated by the membrana tympani from the external auditory meatus. It is a cavity, etc." On the other hand Starling's *Physiology* (1926, p 481) states, "At the junction with the meatus is a special bony ring to which is attached a thin diaphragm, the membrana tympani (or drum), which completely closes the orifice." Perhaps the *Encyclopaedia Britannica* (1929) gives the fairest definition, which is "Drum the word is used of the tympanum or cylindrically shaped middle ear and specially of the membrane that closes the external auditory meatus."

But need my friend carp at a word? He says that he has "little Latin and less Greek." Some 300 years ago a poet laureate wrote, "Thou hadst small Latin and less Greek."—I am, etc.

Gundred

J. K. MILLIGAN.

Homosexuality

SIR.—The correspondence regarding homosexuality has been of great interest to me. I have been fortunate enough to see many hundreds of patients suffering from sexual abnormality, a large proportion of whom were homosexuals. I think that I can claim, therefore, to have had experience at least as wide as any in England. Perhaps you will permit me to add my comments on this matter.

First with regard to causation there is evidence that the endocrine element is important, though not a basic cause. For example, in adrenogenital virilism there may be a concomitant homosexuality which disappears after adrenalectomy (as was pointed out in Broster's *Adrenal Cortex and Intersexuality*, Chapman and Hall). Also some homosexuals, though only a few have glandular dystrophies—e.g., Oscar Wilde was excessively fat and from photographs appears eunuchoid. Again, Terman found that glandular development was delayed in intellectual boys and many homosexuals are of this type. From the psychological point of view the suggested causation of the parents wanting a girl and so educating the boy to be feminine in my experience never occurs. This is shown by the fact that Broster and I have had cases of pseudo hermaphroditism where children have been brought up entirely as girls (including the dress, etc.) but have presented a masculine psyche. Microscopy of the gonads after operation has shown that they were really males. The true factor, as your correspondent Dr. Gilsenan points out, is in the home circumstances. The parent of the same sex as the patient is antipathetic to him. This is my almost invariable finding. This leads to the patient failing to mould himself upon this parent, and instead he unconsciously moulds his mind on (in psychological terminology, "introjects" or "identifies" himself with) the parent of the opposite sex. This occurs from earliest childhood, and hence the idea of being "born homosexual" which many patients elaborate. The result is that the man acquires feminine traits and is capable of loving only those of the same sex. One can see this strongly in those educated in an entirely feminine environment, and perhaps the homosexuality of the East may be the result of educating the boys in the harem until puberty.

No doubt there are other factors, such as assaults at puberty and so on, which tilt the scale. With regard to those correspondents who find no traumatic results to this I think that probably their optimism is due to lack of experience. I have several times found assaults at puberty to be important in causation and in any case the victims often feel degraded, inferior, and unhappy for the rest of their lives. I heard only this week of a man who committed suicide after a life-long sense of degradation due to an assault by another man many years previously.

With regard to treatment I have found as your other correspondents, that psychotherapy is possible only when there is a strong desire to be cured. When this is present I have managed to cure some cases in a few months, but others take as long as two years' hard work, and a large number, of course, are incurable. The difficulty often is, as I pointed out in my monograph, that the patient builds a homosexual environment;

does a feminine type of work such as dress designing; has homosexual friends; even wears feminine underwear, and so on. One must reconstruct his whole life to cure him.

The effect of imprisonment on homosexuals is socially important. I have seen many patients who have been imprisoned but have never seen one who has had any form of psychotherapy by the prison doctor: perhaps those who have had it have been cured—but I wonder. In my own experience they have all been made worse by incarceration. This also is the finding of Fishman (*Sex in Prison*, National Library Press, U.S.A.), Healy, and others. The animal experiments of Jenkins (*Genetic Psychological Monographs*, 3, 457) suggest that imprisonment and seclusion from those of the opposite sex will invariably lead to increase of perversion, and so the final result of incarceration endangers and does not protect the public. Surely it is time that some form of psychosexual institute was founded in London so that this group of illnesses could be studied and treated. I am sure that most public-spirited psychiatrists would lend their help to its foundation and establishment.

In conclusion might one suggest to those who are so indignant that there are such things as perversions that no physician should find a disease "foul," "revolting," and so on, and obtain satisfaction in calling those who have it abusive names. Cholera, syphilis, and lupus are all horrible conditions, yet we try to show the sufferers some little humanity. When one sees a pervert should not one say, as Isaac Newton said of the reeling drunkard, "There but for the grace of God go I"?—I am, etc.,

London, W.1

CLIFFORD ALLEN.

SIR,—Dr. John J. Fitzpatrick (March 9, p. 368) and Dr. W. Lumley (p. 369) are surprised that the "victim" of the homosexual does not always suffer a psychological trauma. If they re-read my letter (Feb. 23, p. 289) they will note that I used the words: "To protect a youth from such an experience is very important; but the normal boy will not be blighted for life if he is unfortunate enough to have been on terms of sexual intimacy with a homosexual man." The significant word of course is "normal." The boy who is not normal and who has homosexual tendencies, psychoneurotic traits, or other disability will almost certainly be harmed by the experience. The normal boy, on the other hand, even though he acquiesced at the time and later regrets the experience, is in a different position; his memory of the affair remains at a conscious level, an adjustment has been made to it, and it has not led to pathological repression and mental conflict. Dr. Lumley presumably thinks that every person—boy, man, girl, or woman—who has indulged the sexual appetite in company with a homosexual suffers a grievous and lasting injury. My observations do not confirm this view. It would be interesting to know on what theoretical basis and clinical knowledge it rests.

Dr. Lumley infers, unjustifiably, that I regard the homosexual assault with complacency. For reasons which may be clear to me, if not to others, he considers it pertinent to ask if I have thought of my own. The answer is Yes. He is shocked by the fact that "there are other factors in such relationships; that sexual activity may play a minor part in a friendship which often has in it much of value." Homosexual activity, involving physical contact between a man and a boy, is always objectionable. "To protect a youth from such an experience is very important"—if I may quote my previous letter for the second time. But to conclude that every friendship between a homosexual man and a boy, even though it may have been soiled by a manifest sexual act, has in it nothing of value is to be misinformed of the facts. Many homosexual men have done magnificent public and private work for boys and have never indulged in any physical act of homosexuality. Other homosexuals have done equally good work, but it has been clouded by some lapse. Not every homosexual is the monster Dr. Lumley believes him to be. Dr. Lumley is comforted to know "that the boys of Edinburgh are safe for fourteen years." The sentence, in this case, was not for fourteen years, but for a much shorter period. From reading the medical and other evidence given at this trial it seems clear that the public work among boys of the (now) prisoner was valued over many years by responsible people. And the same is true of many (though certainly not of all) homosexuals.

A main issue in this correspondence is whether the homosexual should be treated as a criminal or in some other way. Clear thinking, free from emotional preoccupations and based on observation, is essential.—I am, etc.,

London, W.1.

E. A. BENNET.

SIR,—You are to be congratulated on opening the columns of the *Journal* to a discussion of homosexuality. It is a topic that badly needs ventilation—in common with a good many other sex problems. As the subject is one in which comprehensive statistical material is not easy to obtain, individual observations on any aspect are to be welcomed.

The views put forward by Dr. E. A. Bennet (Feb. 23) on the effect of homosexual seduction on young people are not held by him alone, and to describe them, as Dr. W. Lumley does (March 9), as "obscene balderdash" is not only offensive but out of place in a presumably scientific discussion and outmoded by 30 years or so. Instead of emotional thinking, if Dr. Lumley has any evidence to the contrary let him bring it forth.

Rosanoff, for example, writes: "As to other early conditionings, such as seduction by older boys or by homosexual men, the evidence of their effectiveness is more largely negative than positive. It seems as difficult to turn a heterosexual boy homosexual as to accomplish the opposite feat; although, of course, it is an easy enough matter to seduce a child sexually along almost any direction. Cases of seduction can be gathered literally by the thousand; but such evidence as is available would seem to indicate that such seduction can only be of lasting effect if its direction corresponds with the inherent sexual tendencies of the subject" (*Manual of Psychiatry*, 7th edition, 1938, p. 556). What I consider should be added is that the experience is liable to produce a conflict which contributes to the development of a neurosis in later life. The same writer further maintains: "A homosexual component constitutes an integral part of the sexual make-up of almost all, if not quite all, individuals—perhaps the total absence, or unusual lack, of a homosexual component is as abnormal and, in its special way, as handicapping as is an unusually large such component" (*ibid.*, p. 554). Obviously a statement likely to arouse a good deal of discussion, which should be very helpful if conducted on rational lines.—I am, etc.,

London, W.1.

FREDERICK DILLON.

SIR,—The attitude of your correspondents has been characterized by either aggressive denunciation of a harsh sentence and sentimental impotence in regard to the general problem of homosexuality, or a marked hostility towards an enemy of society without consideration for the medical aspects of the case.

The suggestion that many homosexuals can be treated successfully is highly optimistic. The constitutional homosexual is incurable, and therapy is a complete waste of time except in so far as it may remove or relieve concomitant neurotic features. In other words, treatment may convert an unhappy homosexual into a happy or less unhappy one, but will not affect the homosexual constitution of the patient. But, even if therapeutic optimism were justifiable, the legal aspects of homosexuality must still be considered. The law is concerned with antisocial acts and the protection of the public. Medicine is solely concerned with the treatment of the patient. The two aspects must not be confused. The obvious answer to the problem is segregation and treatment.

It is unfortunate that one medical man should regard homosexuality as an "ugly vice" and that another should advise "castration as a cure in the worst cases." The attitude of the former is unlikely to advance scientific progress or enable him to deal sympathetically with any of his patients who may happen to be victims of sexual inversion. "The admirable remedy of castration" is probably not disregarded "because medicine and law are ignorant," but for the reason that such treatment would be most likely to accentuate passive tendencies which are innate in most homosexuals. The persistent homosexual seducer of our youths must be segregated, permanently if necessary, but the first offender should be regarded as a psychiatric case and remanded for appropriate treatment.

Acrimonious diatribes and the expression of violent prejudices will neither stimulate our legislators into changing the

law, encourage the wretched homosexual to seek treatment, nor increase respect for the medical profession. Besides, some of your contributors should realize that their vitriolic rhetoric in the denunciation of homosexual practices represents a violent repudiation of their own repressed homosexual tendencies.—We are, etc.,

London, W.I.

ELLIS STUNGO.
EUSTACE CHESLER.

SIR,—As a senior student at a large teaching hospital I find that the attitude of my contemporaries towards homosexuality varies quite considerably. Some are naturally biased, while others regard it with an open mind; but all, I think, realize that a sympathetic understanding of the subject is of the utmost importance.

But is an entirely satisfactory solution to the problem to be found in a closer collaboration between the medical and legal professions, or in either profession individually? They deal primarily with what one might term the "mature" homosexual. There would appear to be opportunities for prevention, thus alleviating the necessity for cure. A substantial proportion of homosexuals owe their condition to a number of various influences during their schooldays. These influences are liable to be particularly strong at a boarding school. School teachers, therefore, especially those in charge of the welfare of boys and girls out of school hours, hold a position of great responsibility. Some of them can, and do, discharge their responsibility to good effect when necessary. But there are others who, although willing to play their part, are sadly lacking in a sound knowledge of sexual aberrations, or those to whom, on the other hand, anything in the nature of a homosexual practice is a heinous offence meriting immediate expulsion. And, further, there are a few—sometimes conscious of their peculiar condition—who choose teaching as a career because they have homosexual tendencies themselves; it is the maladjusted members of this group who are a potential source of danger. It does seem a mistake, as is the case in one school I know of, to allow only unmarried men to be housemasters.

In some schools the state of affairs is lamentable; there is often no one to whom a troubled boy or girl can turn for help or advice. I happened to be at a public school where the headmaster regarded the whole problem in a sane and balanced manner and at which the biology master gave excellent courses of lectures on sex to boys of all age groups. It is at school, where no sexual practice among boys or girls can really be dignified by the word homosexual, that an understanding attitude would be of inestimable value. The adolescent is far more amenable to advice than the adult is to treatment. Is it not the teaching profession, assisted by doctors, which can do the most good?—I am, etc.,

London.

RODNEY H. N. LONG.

Are the People More Healthy?

SIR,—The account and appreciation of the "Survey of Sickness" which you published in your leader on March 2 (p. 318) is welcomed by the staff of the Social Survey who are carrying on this work. I am sure it is equally welcome at the Ministry of Health, where the data collected by the Survey on the state of the nation's health are reviewed and published. Above all, it will be welcomed by our interviewers, to whom public recognition of the value of their work is a great encouragement. The samples of 2,000 to 2,500 people are admittedly small to furnish reliable statistics. Whether they are too small cannot be discussed without reference to particular problems for investigation—for instance, whether the incidence of any given illness is unexpectedly high at a particular time or in a particular section of the population is a problem which would need careful handling. It is true to say that the number of problems which could be effectively studied would be increased if the samples were enlarged. But the cost of interviewing is the chief item in the cost of the surveys, and decisions to enlarge the sample are dependent on financial considerations. The representativeness of the samples is ensured by selecting names by a standard drill from the cards held in local offices for national registration. Continuity in this basic method of sampling increases the reliability of statistics of periodic fluctuations. But all the information collected relates only to

the civilian population of England, Scotland, and Wales from 16 to 64 inclusive. Thus the population samples have been subject to gross changes during the period under observation.

Among our reasons for reposing confidence in the classifications of illness for the Survey are the three following. First, the interviewers record a description of every illness and particulars of its history in addition to the name assigned to it by the informant (which is often a repetition of the doctor's statement after examination). These records are passed to the Ministry of Health, where the recorded illnesses are classified according to the Medical Research Council code. This procedure preserves a high degree of consistency in the classifications. Secondly, the interest of the work attracts able people for appointment as interviewers, and they receive thorough training. The schedules they use and the instructions they follow have been rendered comprehensive and precise through cumulative experience. Their work is conscientious and always checked. Thirdly, evidence has established the reliability of information on health collected by survey methods. In an investigation made by the U.S. Public Health Service, 90% agreement was found between statements from the family and from the physician (Perrott, G. St. J., Tibbitts, C., and Britten, R. H., *U.S. Public Health Reports*, 1939, 54, 1663). The family statements used in that investigation were obtained under less favourable conditions than ours.

The information so far published has been extracted by officers of the Ministry of Health. It deals mainly with general rates of incidence of broad classes of illnesses. Articles by Dr. Percy Stocks in the *Monthly Bulletins* of the Ministry of Health are the main references. No information showing the associations between sociological data collected during the interview and data concerning the incidence of illnesses has yet been published, but the Social Survey is examining the available data of this kind and will publish a detailed report shortly.—I am, etc.,

The Social Survey, London, W.I.

PATRICK SLATER.
Senior Research Officer.

Fundamental Principles and Errors of the Medical Profession

SIR,—Impressed by the imposing list of bodies whose representatives compose the Negotiating Committee, I read the first page of the *Journal* of Dec. 15, 1945, with great expectations. I was correspondingly disappointed, therefore, to discover two fundamental errors in the preamble to the fundamental principles. The first is the use of the phrase "complete health service" where, I submit, "complete medical service" is what is meant. The second error occurs in the lamentable third paragraph, which omits education as the principal factor in the health of the community, and gives first place to "good housing," which is, after all, only one of the "environmental circumstances."

As a council member and office holder of the Victorian Branch of the B.M.A. I have been considerably involved in our local struggle against regimentation, and as lecturer in hygiene at the Melbourne University have given considerable thought to the vital distinction between "health services" and "medical services." It is, I suggest, obvious that all public services are health services in that they have no justification other than to further the well-being of the community. Medical services, including those of doctors in the public health services, make an important contribution to the health of the people, but this is determined mainly by education and by economic factors. Medical men as such obviously cannot remedy the causes of "deficiency disease" in general, still less the "psychological factors" which are so vast a cause of illness. The present tendency of politicians and agitators is to support the idea that what is mainly needed to remedy the ills and unhappiness of the people is more doctors, hospitals, and free medicine; but the profession must not be so foolish as to assume responsibility for the health of the people. Flattering though the idea may seem.

It should be unnecessary to argue in detail that education in its wide and proper sense is a primary essential for the well-being of a community. Granted that the physical requirements for growth and protection are available, which is a matter of economics and social organization, the primacy of education

surely cannot be disputed. It is only by educating—that is, by providing opportunities for the full psychosomatic development of each unique precious individual—that we can hope to achieve a community of positively healthy, self-respecting, intelligently co-operative citizens. Self-respect must be based on successful achievement, socially useful or creative in character. Schools must be such that every child can be good at school, and has to be dragged away from it. It is encouraging that Britain has apparently planned improvements in its educational provisions. It is surely the duty of the profession to foster and encourage those provisions, in the conviction that the teachers will make a greater contribution to the health of the community than can doctors as such.—I am, etc.,

Melbourne, Australia.

JOHN DALE,
Medical Officer of Health.

Lay versus Medical Administration

SIR,—Both Sir Frederick Menzies (Feb. 16, p. 251) and Dr. F. J. Bentley (March 2, p. 327) are looking at this matter from the point of view of the medical profession. Of course it is in the interests of doctors to have medical administration, which will always favour the medical man. From the wider point of view of the interests of the community there is not much doubt that lay administration is preferable for the following reasons:

(1) It is cheaper. (2) It is more likely to be efficient since the only consideration in choosing a lay administrator is his ability to administer, while in the case of doctors much more weight is apt to be attached to their professional qualifications than to their administrative ability. (3) Medical administration is so often, alas, the refuge of the incompetent who is neither a good doctor nor a good administrator. (4) Of the work at the central offices of a large National Health Service 99% will be clerical and executive. Medical work will be done in hospitals and clinics. It is a sheer waste for highly qualified medical men to spend their time and energies on clerical processes.

Sir Frederick Menzies is fundamentally wrong when he says that the problems to be dealt with in the new regional organizations are and will always be predominantly medical—they are not. The problems will be problems of administration, pure and simple, and will be precisely the same problems of administration as arise in any large organization. There will be ample scope for the doctor in the new National Health Service, first in his proper sphere—i.e., in the active practice of his profession of medicine—and secondly in an expert advisory capacity. But for Heaven's sake don't let him spill over into the sphere of clerical work and waste his special talents in a field where he is not at his best.—I am, etc.,

Epsom Downs.

C. E. NICOL.

Diuresis by Suggestion

SIR,—The doctrine of signatures has had many believers through the ages. In bygone days, or in other places, to eat the heart of a lion was to acquire the courage he was thought to possess; or, to jump to contemporary usages, I have sometimes thought that by the same token the viscid syrup of tolu commonly included in expectorant mixtures to "cut the phlegm" it resembles. But a more striking instance was recently recorded in your always interesting "Nova et Vetera," where the successful treatment of a case of dropsy by drinking water was described—the water cure. I suspect much was omitted, as is suggested by a case at present under my care. She is a lady of 85 who suddenly developed typical acute congestive heart failure with so much oedema of her legs and thighs that she could not move them. "Try to pass plenty of water," I said. "I can't," she replied. "But try," I urged; "I will help you with some medicine." I made up for her a weak aqueous solution of pot. brom. and pot. cit. which I did not flavour or colour. It must have tasted bad but it looked just like water. I relied on my supposed prescience as a registered medical practitioner. Anyhow it worked and a prodigious urination began. In a few days all the dropsy had gone and she could move her legs freely.

Some important details are omitted in the way the patient was handled, but I believe the happy re-establishment of her circulation was solely the result of suggestion—a strange process in which depends an immense amount of therapy, though often unconscious. How often does suggestion work? It seems to me that there can be only one way. The natural powers of

healing; the natural tendency to restoration after injury or impairment; the *vis medicatrix naturae*—somehow they are stimulated or even tricked into activity.—I am, etc.,

London, S.W.1.

E. GALLOP.

Motive in Medical Demobilization

SIR,—In his letter (March 9, p. 371) on "Motive in Medical Demobilization" Sir Ernest Graham-Little states that the Minister of Health will have "in the bag" some thousands of ex-Service doctors who have been subjected to continuous unilateral Socialist propaganda in which a State medical service has been a primary objective. As a doctor lately released from the Royal Naval Volunteer Reserve I have come in contact with many doctors in the Navy, and I have not met one who has been imbued with Socialist principles. I am happy to say that I neither saw nor heard of organized political propaganda within the Service. I am quite certain that the majority of demobilized doctors, who during their service have been drafted round the ends of the earth from pillar to post, are quite unfavourable to any form of State medical service as devised by the Socialist Party.—I am, etc.,

London, W.8.

W. D. G. TROUP.

Child Welfare in Singapore Internment Camp

SIR,—I read Miss Mary Thomas's letter (March 9, p. 371) with much interest, and thank her for her generous account of the work of the medical women in the Singapore internment camp. As she refers to a certain disagreement in the camp in which I took a large part, and as there is naturally no account of the case raised by my opponents, I ask you to allow me to state it.

The mothers of children interned in Changi Jail were in a peculiarly difficult position. An appallingly overcrowded jail is a bad home for a child, and the conduct of our children naturally deteriorated. The shortage of the necessities of life sometimes made their normal child-like activities disastrous. And there was added irritation in the fact that members of a family could not get out of sight and sound of each other. All the mothers were harassed, especially those with large families. The opposition to my proposal was that I was giving publicity to the failings of some sorely tried members of the camp.

May I add what I know Miss Thomas would endorse—that of the elect company of those whose conduct was an unflinching inspiration to the camp a goodly number were Eurasian women.—I am, etc.,

Whitney.

PATRICIA R. ELLIOTT.

Universities and Colleges

UNIVERSITY OF MANCHESTER

Dr. J. Crighton Bramwell, F.R.C.P., who will complete his period of appointment as professor of systematic medicine at the end of the present session, has accepted the invitation of Council of the University to become professor of cardiology from September next.

Dr. T. H. Oliver, F.R.C.P., whose period of appointment as professor of clinical medicine will be completed in September next, has accepted the Council's invitation to become professor of therapeutics from that date.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Dr. Maurice Campbell will deliver the Lumleian Lectures on Tuesday, April 16, and Thursday, April 18, at the College, Pall Mall East, S.W., at 5 p.m. Subject: "The Paroxysmal Tachycardias."

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

On March 14 the Right Hon. Thomas Johnston, lately Secretary of State for Scotland, and the Right Hon. Florence Horsbrugh, Parliamentary Secretary to the Ministry of Health 1939-45, received the Honorary Fellowship of the College. Diplomas of Honorary Fellowship were also conferred on Dr. Andrew Davidson, F.R.C.P.Ed., chief medical officer, Department of Health for Scotland; Mr. Eardley Holland, F.R.C.S., President of the Royal College of Obstetricians and Gynaecologists; Sir Edward Mellanby, M.D., F.R.S., secretary of the Medical Research Council; and Air Marshal Sir Harold Whittingham, Director-General, Medical Services, R.A.F. The President of the College, Mr. J. M. Graham, took the chair at the ceremony. Each of the recipients after being presented and given the diploma made a brief speech of thanks.

Obituary

ADOLF LORENZ, M.D

Prof G GREY TURNER writes

The death of Adolf Lorenz of Vienna at the age of 91 removes a great pioneer in orthopaedics and a colourful figure from the realms of surgery. At the time of my first visit to the Austrian capital in 1899 Lorenz already enjoyed a wide reputation, especially in connexion with congenital dislocation of the hip. He had consulting rooms in the same apartment house in which I lodged and there were always numbers of his patients hanging about, either waiting to see him or discussing among themselves the result of their consultation or treatment. Even at that time many of these people had come from distant parts and especially from America to be under his care. At the Allgemeine Krankenhaus not only was he in charge of wards and had an out-patient department but his visits were always eagerly expected and there were many visitors. No arrangements were made for the convenience of the students, who clustered round this tall outstanding man, distinguished by a long and voluminous beard. This crowding round the teacher was usual in Vienna, for I especially recall the cosmopolitan crowds round Politzer, of otological fame, and Chian, the laryngologist, at the Polyclinic.

Lorenz only stayed about a couple of hours, during which time he saw quite a lot of patients and carried out one or two of his bloodless operations. The gross manipulation in a case of wry neck has always remained in my recollection as a very crude business and not to be compared with the simple open operation. But his reputation as a pioneer in the management of congenital dislocation of the hip can never be assailed, and I am old enough to recall the parlous state of sufferers from that malady before Lorenz pointed the way to cure. In his clinic all was bustle and volubility while the chief demonstrated, but when he left relaxation was the order of the day. Thereafter we befuddled the innocent visitor who fell into the trap when asked if he would like a little practice in plaster work for the business of changing and renewing plasters went on for hours. He had been trained for a career as a general surgeon, but the story was then current that he was driven to develop bloodless surgery because his skin was so susceptible to antiseptics of all kinds. As a result he suffered from severe attacks of dermatitis after working in the operating theatre and found that he would have to adopt some other branch of professional activity. In later life he made rather a joke of his methods and twitted the surgeons who, he said, "loved streams of blood," while he boasted that he never wasted a drop.

His old friend Robert Jones was present when I next saw Lorenz at work, in 1912, and they had a rare time together. On that occasion Lorenz demonstrated a large number of cases showing the after results of manipulative treatment for congenital dislocation of the hip. He had these patients walk round and round a table and invited the visitors to identify the side which had been affected. One patient had come from America, and Lorenz was vastly amused when Robert Jones was puzzled in deciding which side had been treated. As the moments passed Lorenz got more and more excited, stroking his long beard the while. Finally he burst out laughing as he informed the company that it had been a bilateral case. Lorenz's reputation in the surgical world undoubtedly suffered after an early visit to America when he went over to treat the daughter of one of the great packing houses. I have heard a good deal about that visit, and always feel that he was unfairly treated by the newspaper men, who were really responsible for some of the rather crude and reprehensible things that were blamed on to poor Lorenz.

ROBERT KLÄBER, M.D, FRCP

Dr Robert Kläber, who died suddenly at his home in London on March 2 at the early age of 45, had already made his mark in dermatology. The son of Augustus Kläber he was born at South Norwood on Dec 24, 1900, and was educated at Tonbridge School and for two years edited the school magazine. He had a distinguished student career at St Bartholomew's Hospital, where he won the Burrows and Skynner prizes and was *proxime accessit* for the Brackenbury medical scholarship. He graduated M.B., B.S. in 1924, took the MRCP in 1927 and the MD a year later, and was elected FRCP in 1941. After qualifying he served as house-surgeon and house physician at the Radcliffe Infirmary, Oxford, and casualty officer at the Royal Northern Hospital, and took the DPH and the DTM&H. In 1929 he was appointed junior demonstrator in

pathology and clinical assistant in the skin department at Bury's and later chief assistant there, and was elected physician to the skin department of the Prince of Wales's General Hospital, Tottenham. He also lectured on dermatology at the associated North East London Postgraduate College.

When war broke out in 1939 Kläber took up duty as consulting dermatologist to Sector 2 of the Emergency Medical Service, and he organized a skin unit when the Havre de Grace Hospital at Bishops Cleeve was upgraded. He was an active member of the British Association of Dermatologists and Syphilology and had been secretary to the Section of Dermatology of the Royal Society of Medicine. He published a number of papers on skin diseases, including an account (written jointly) of the pathogenesis of rosacea. Apart from his main hospital appointments he had been consultant to the L.C.C., to the Harrow and Wealdstone Hospital and the Bishop's Cleeve General Hospital, and more recently to the Luton and Dunstable Hospital.

W F NEIL, M.B., F.R.C.S

Mr William Fulton Neil died at his home in Nottingham on Jan 21. He was born at Dunedin, New Zealand, in 1882, and after qualifying there came to England and obtained his F.R.C.S. in 1910, and then came to Nottingham as house-surgeon. After serving in the 1914-18 war and attaining the rank of major, he returned to Nottingham and was quickly promoted to the honorary staff of the General Hospital. At the time of his death he was chairman of the Medical Committee. A few years ago he was the president of the Nottingham Medico-Chirurgical Society and also president of the Surgical Union of Great Britain. He was consulting surgeon to the E.M.S.; consulting surgeon to the Ilkeston Hospital, the Heanor Hospital, and the Skegness Hospital. He was a Justice of the Peace, and a past chairman of the Nottingham Division of the B.M.A. Mr Neil was due to retire in March and was looking forward to paying a visit to his relatives in New Zealand. He had been in failing health for some months, but remained in active practice and continued to take unabated interest in hospital affairs until a few days before his death.

His death (writes a colleague) removes one of the best-known surgical specialists in the East Midlands, and a man of more than local fame. Having perhaps no hobbies, he devoted himself to two ends—the welfare of the Nottingham General Hospital and the welfare of his individual patients. He had that gift of obtaining a patient's absolute confidence. His interest was focused chiefly in gastric surgery, and he was one of the pioneers of this art and its modern developments in the Midlands. His practice was large, but his solicitude for the individual was never perfunctory, nor did his interest end when the patient left the theatre. He was prepared to operate at an early hour in the morning, to continue in the theatre throughout the day, and finish at a late hour at night, and only a man of his physique and capacity for work would have been able to carry on as long as he did. His singular devotion to duty undoubtedly accelerated his death.

His colleagues on the hospital staff and innumerable patients will have heard of his death with the deepest sense of loss, mourning not only a brilliant surgeon but the kindest and most generous of men. In 1915 he married Miss Eva Kerr-Smith, a sister at the hospital, and he is survived by his widow and three children, a son and a daughter being qualified and serving in the R.A.M.C.

WILLIAM MCKEE BONNAR who died on active service in India as the result of a flying accident, qualified with second-class honours at Queen's University, Belfast in 1939. After spending terms as house-surgeon and house-physician in the Royal Victoria Hospital, Belfast, he moved to the Department of Physiology, Queen's University, as demonstrator in physiology. While in this position he wrote a thesis which gained him his M.B. with gold medal. He joined the R.A.F. in 1942, and after some time in Great Britain was eventually sent to India. One of the most brilliant students of his year, he combined a high talent with great self-discipline in the use of it. He will be remembered by his friends, not only for his academic attainments, but for the quiet, unassuming depth of his character.

The following well-known medical men have died abroad. Dr JOSEPH MCFARLAND, emeritus professor of pathology at the University of Pennsylvania, aged 77; Dr ELLSWORTH ELIOT, jun., past-president of the American Surgical Association, aged 81; Dr S. N. TCHERNOZ, professor of biology at Zürich University; Dr SZILAS, a Budapest ophthalmologist, and Dr E. E. MARR, professor of the history of medicine at Copenhagen University, aged 68.

Medical Notes in Parliament

Smallpox Cases Aboard Ship

Mr. THOMAS BRADDOCK asked on March 7 whether the R.A.M.C. officer at Hampstead who "gave" his wife and daughter smallpox infection had been vaccinated, whether the R.A.M.C. sick-berth attendant who infected his nephew with smallpox at Grays had been vaccinated, and whether the three cases of infection which developed from these two members of the R.A.M.C. were in vaccinated persons. Mr. BEVAN replied that all the persons mentioned had been vaccinated at some time, though dates of last vaccination varied considerably, as did the severity of the attacks.

In a further question Mr. BRADDOCK asked how many cases of smallpox had been landed in the Mersey from a ship arriving from India, how many of the crew developed smallpox and were put ashore at Suez, and what was the vaccinal condition of the cases of smallpox that developed in this ship. Mr. BEVAN assumed that the ship referred to was the *Empress of Australia*. He learnt that one case of smallpox (a member of the crew) was landed at Liverpool on Feb. 18. No member of the crew developed smallpox and was put ashore at Suez, but two cases and one suspected case (not members of the crew) were landed there. He had no information as to the vaccinal condition of the patients landed at Suez, but was informed that the patient landed at Liverpool was vaccinated in infancy, and had been revaccinated several times during the war but without the vaccination taking.

Tropical Diseases: Temporary Hospital Premises

Presenting on March 11 a Supplementary Estimate for Colonial and Middle Eastern Services, Mr. CREECH JONES said one item in the Estimate was concerned with the Seamen's Hospital Society in London. It represented the balance of a loan to enable the Society to re-establish in London a hospital for tropical diseases. At present hardly any accommodation was available for patients suffering from these diseases. It was desirable that patients should be treated near the School of Hygiene and Tropical Medicine in Central London. The tropical diseases hospital in Endsleigh Gardens, which was requisitioned by the Ministry of Health in 1939, was now declared by the Ministry to be unsuitable for use as a hospital. It was proposed to go ahead with a new tropical diseases hospital, but it was only at the planning stage. As an interim measure the Seamen's Hospital Society had acquired 23, Devonshire Street, which had accommodation to provide a maximum of 40 beds. The Society had not the funds to meet this cost and the Treasury had agreed that a short loan of £60,000 should be made. The Government now asked that a second loan should be available. He hoped this would be repaid comparatively soon.

Dr. MORGAN said there were already four institutions in London dealing with tropical diseases—the Seamen's Hospital in Greenwich, the Postgraduate Medical School, the hospital which used to exist in Endsleigh Gardens, and the School of Hygiene and Tropical Medicine. This temporary grant was a waste of money. It would be better at present to use beds in ordinary hospitals instead of lending money to reconstruct an old house in Devonshire Street. Mr. OLIVER STANLEY was surprised that it was worth while to make this loan seeing that it had to be repaid at the end of the year. While he was at the Colonial Office a small committee considered a long-term project concerning tropical diseases. They were in search of sites, but there was no question of a reconditioned house. The aim was something much bigger and better.

Replying, Mr. CREECH JONES said a big tropical diseases hospital was being planned. In the interim it was proposed that 23, Devonshire Street should be acquired. That was a modern building and would give the Seamen's Hospital Society a nursing home which could be readily transformed into a hospital.

The House approved the Estimate.

Release of Doctors

Mr. TURTON inquired on March 13 how many R.A.F. medical officers were specialists and on that account "frozen" from the operation of the Class A release scheme. Mr. J. STRACHEY replied that there were 134 R.A.F. medical officers filling specialist posts. The Air Ministry had told those who would otherwise be due for release up to the end of May—74 in all—that they would have to keep them on under the "military necessity" clause. The Central Medical War Committee was calling up specialists, for a period of 18 months, who had not yet served in the Forces and were over 30 years of age. The Air Ministry rusted that it would receive a sufficient allocation of these new

entrants to enable it to release as many as possible of its own specialists. It was also accepting volunteers aged 40 and over for a similar period of service.

An assurance that the present quota of new recruits to the R.A.F. medical branch is adequate was requested on March 14 by Mr. ALLIGHAN. He further asked what were the quotas of new medical officers originally decided upon for each of the three Services for the first half of 1946, and what adjustment was to be made in view of the disparity in the release rates of general duty medical officers. Mr. BEVAN said that provisional quotas for the first half-year, 1946, were Navy 60, Army 280, R.A.F. 110. The question of adjusting the quotas, including particularly the adequacy of the intake to the R.A.F., was being considered by the Government. These quotas applied to young practitioners up to the age of 30. In addition the recruitment of specialists continued over the age of 30 to provide substitutes for specialists in the Forces who could not be released without replacement.

Mr. A. V. ALEXANDER furnished on March 11 a table of estimated monthly releases from the Royal Navy, which showed the latest dispersal dates for medical officers to be April 30 for Groups 48 and 49, May 31 for Groups 50-52, and June 30 for Groups 53-55.

Pleurisy and Erythema Nodosum: Notification

On March 14 Dr. BARNETT STROSS asked whether the Minister of Health would cause the conditions of pleurisy, phlyctenular conjunctivitis, and erythema nodosum to be made subject to provisional notification to assist in the prevention and treatment of tuberculosis. Mr. BEVAN replied that the desirability of bringing these conditions to the attention of the tuberculosis service was recognized, but this would not be achieved simply by instituting a procedure of notification. The important thing was that general practitioners should be fully aware of the significance of these conditions in relation to tuberculosis, and should encourage recourse to the specialist facilities of the tuberculosis service whenever they were encountered. He was considering what he could do to help in this.

Silicosis with Tuberculosis

In an answer on March 14 to Dr. STROSS, Mr. JAMES GRIFFITHS reported that in the twelve years 1933 to 1944, 19% of the workers in the pottery industry who were certified by the Silicosis Medical Board were found to be suffering from silicosis accompanied by tuberculosis. In cases of silicosis, tuberculosis could become manifest after certification. The experience of the Medical Board in North Staffordshire was that the average period between certification and death, in which death was found to have been caused by silicosis accompanied by tuberculosis, was just over two years. In cases of silicosis alone it was five to seven years. In the individual case the period depended largely on the workman's age and the degree of his disablement at the time of certification.

Tuberculosis in the Navy

The following table gives the totals of officers and men who were invalided out of the Navy with tuberculosis in the years 1939 to 1945.

Year	Officers	Ratings	Total
1939	11	213	224
1940	30	441	471
1941	33	811	844
1942	67	1,364	1,431
1943	87	1,553	1,642
1944	142	1,843	1,985
1945	101	1,565	1,666
Total ..	471	7,792	8,263

The figures include Royal Marines. Separate figures for warrant officers are not readily available, and they have, therefore, been included with the officers.

Medical Students under Government Training Scheme.—Applications received up to March 5 under the Government Further Education and Training Scheme included 904 with medicine as the professional career in view. Of these applicants 185 received awards. For dentistry, applications were 209 and awards 53; for pharmacy, applications 181 and awards 34; for training as radiographer, applications 66 and awards 19; for occupational therapy, applications 202 and awards 56.

Specialists in West African Command.—Sir ERNEST GRAHAM LITTLE on March 7 asked the Secretary for War to inquire into the position of specialist medical officers in West Africa at present employed on general duties, largely administrative. Mr. LAWSON replied that because of the scattered nature of the West African Command it was impossible to secure concentration of specialist facilities. It

was necessary to maintain an adequate specialist establishment at a number of centres. This meant that some specialists would not always be employed full time on specialist duties. In such cases a specialist was required to undertake a share of general medical duty. Mr Lawson added that he would ensure that any specialist who was being employed whole time on general duties was either repatriated to the United Kingdom for release or transferred to another command where he could be employed in his specialty.

Punishment of Borstal Boy by Restricted Diet—Mr G LANG on March 12 raised the circumstances of the death last November of a Borstal boy of 19. He said the boy had been severely punished and later was transferred to another institution where he died despite careful and complete medical attention. This boy had been put for 30 days on restricted diet, and the medical evidence later used the word anaemia. Mr CHUTER EDE said the inquiry into this case had been conducted by Judge Eastham, a lawyer who held medical degrees. Mr Ede confessed that he was concerned at the infliction of severe dietary punishment on growing boys and girls and intended to have a careful investigation into it, although there must be effective means of maintaining discipline.

Medical News

If the Government's Bill for a National Health Service has been published by Friday, March 22, a meeting of practitioners resident in Wandsworth, Kingston, Richmond, Croydon, Reigate, and Guildford Divisions will be held in Wimbledon Town Hall at 2.30 p.m. on Sunday, March 24. This meeting, which will be open to members and non-members of the Association, will be addressed by Dr Charles Hill, the Secretary of the Association. The subject will be 'The Profession and the Bill'. Dr Hill will also speak at professional meetings in Bristol on March 27, in Lambeth Town Hall on March 28, at Stoke-on-Trent on March 29, Manchester on March 30, Liverpool on March 31, St Albans on April 2, B.M.A. House, London, on April 4, in Edinburgh on April 6, in Glasgow on April 7. He will address public meetings in Bristol on March 27, in Stoke-on-Trent on March 29, in Bournemouth on April 10, in London on April 11, in Tunbridge Wells on April 16, in Norwich on April 17. These meetings will be the subject of local announcements giving fuller details.

A meeting of the Scottish Group of the Association of Industrial Medical Officers will be held in the Institute of Hygiene, University of Glasgow, on Wednesday, March 27, at 3 p.m. when Dr Myles of I.C.I. will read a paper on "Dust Counting". Medical practitioners and all others interested are invited to attend.

Sir Jack Drummond, Scientific Adviser to the Ministry of Food, will read a paper on famine conditions and malnutrition in Europe at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2, on Wednesday, March 27, at 5.30 p.m. Sir Ben Smith, the Minister of Food, will preside.

The 66th annual meeting of the Mental After Care Association will be held in the rooms of the Royal Society at Burlington House, Piccadilly, W., on Wednesday, March 27, at 2.45 p.m., under the presidency of H.R.H. Princess Arthur of Connaught. The speakers include Dr J. Bram, of the Polish Medical Services; Dr Duncan Whitaker, and Dr Henry Yellowlees, chairman of the association. All interested are invited to attend.

A sessional meeting of the Royal Sanitary Institute will be held at Bedford Town Hall on Thursday, March 28, at 10.30 a.m., when a paper on "Epidemic Disease: Past, Present, and Future" will be read by Dr G. K. Bowles.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital (St George's Circus, Southwark, S.E.) on Thursday, March 28, at 5.30 p.m., when a talk will be given by Dr W. W. Mushin on "Anaesthesia for Ophthalmic Operations". Cases and tea at 5 p.m.

A meeting of the Medical Legal Society will be held at 26, Portland Place, W., on Thursday, March 28, at 8.15 p.m., when a paper will be read by Dr A. Lisle-Punch on "Tuberculosis and the Law".

An appeal will be broadcast in the Week's Good Cause, 8.25 to 8.30 p.m. on March 31 by Mr Basil Henriques, on behalf of St Mary's, Birchington, the Home of Recovery for Diabetics. Contributions should be addressed to Mr Henriques, the Diabetic Association, 9, Manchester Square, W.1.

Prof. Noah Morris, M.D., F.R.S., of the chair of materia medica and therapeutics in the University of Glasgow, has been appointed a member of the Inter-University Council for Higher Education in the Colonies.

Sir Edward Mellanby, M.D., F.R.S., secretary of the Medical Research Council, will give an address on "Medical Research in War and Peace" before the Royal Institution, 21, Albemarle Street, W., on Friday, April 5, at 5 p.m.

Dr C. H. Rogerson, for the past nine years medical superintendent of the Cassel Hospital, has accepted an invitation to go to Baltimore to become clinical director of the new Seton Psychiatric Institute. This is to be run somewhat on the lines of a general hospital with a visiting staff of psychiatric consultants and is also to be a post-graduate training school.

The British Association of Physical Medicine has now been admitted to the Joint Secretariat for Specialist Associations, established by the Royal College of Surgeons, and all correspondence should be addressed to 45, Lincoln's Inn Fields, London, W.C.2. (Telephone: Chancery 6965.)

The Emergency Public Health Laboratory in Oxford has moved to a new building in the grounds of the Radcliffe Infirmary. Communications should be addressed to the Director (Dr R. Knox), Public Health Laboratory, Walton Street, Oxford. Telephone numbers remain as before—Oxford 47884/5.

The Minister of Health states that he is informed by the Ministry of Food that there is no longer any need to restrict supplies of ascorbic acid to hospitals. Circular 73/44 of June 28, 1944, is therefore withdrawn.

An Order (S.R. & O. 1946, No. 250, H.M. Stationery Office, 2d) issued by the Ministry of Education repeals the Mental Deficiency (Notification of Children) Regulations, 1928(c), and prescribes the records and information which should accompany every report made by a local education authority concerning a child examined for disability of mind. The first schedule to the Order contains the form of report required from the medical officer.

A large number of medical officers have reappeared in Belfast Medical School on demobilization. The Dean of the Medical Faculty of the University is chairman of a committee which is endeavouring to deal with the many requests for resident and post-graduate appointments. The opportunity of giving postgraduate instruction has not been neglected, and an intensive course is in operation at the teaching hospitals and the Institute of Pathology. Clinical demonstrations and special lectures appear in the programme for each day of the week.

Papers on the planning and equipment of special libraries given at the 1945 conference of the Association of Special Libraries and Information Bureaux roused so much interest that Aslib has been asked to give a further opportunity for the discussion of these problems. By consent of the Royal Institute of British Architects a one-day conference will be held at 66, Portland Place, London, W., on Saturday, April 6. The planning and equipment of university and college libraries will form the main subject of the morning session; the afternoon will be devoted to similar problems with special reference to research organizations and industrial concerns. An inclusive fee covering both sessions of the conference, mimeographed copies of the papers to be presented (which will be circulated before the meeting), and a buffet lunch and tea at the R.I.B.A. will be 10s. to members of Aslib and of the R.I.B.A. and £1 to non-members. Applications should be sent to the general secretary, Aslib, 52, Bloomsbury Street, W.C.1, as soon as possible.

Prof. G. H. Monrad Krohn, Norway's foremost neurologist, is leader of the Norwegian medical and scientific delegation which has come to England (at the invitation of the British Council) to study advances in medicine and allied sciences made during the years of German occupation of their country. Thirty-three years ago Prof. Monrad Krohn was resident medical officer at the Maida Vale Hospital for Nervous Diseases, and on March 12 he was the guest of honour at a reunion luncheon given by Viscount Davidson, now president of the hospital. He spoke affectionately of his old association with the Maida Vale Hospital, and said that one of his most abiding recollections was that, always the home of research, the hospital made a point of a prompt application of results of research to treatment. Among members of the staff sharing the reunion were Dr Wilfred Harris, Dr Anthony Feilding, Dr W. Russell Brain, Mr Dickson Wright, Mr Wylie McKissock, Dr James Bull, Dr E. A. Blake Pritchard, Dr Redvers Ironside, and Dr S. P. Meadows.

Dr John Orr, who, when he retired twelve months ago, had been Dean of the School of Medicine of the Edinburgh Royal Colleges for 21 years, has lately received gifts from students and lecturers of the school in recognition of his deanship. The presentation was made in the Hall of the Royal College of Surgeons in the presence of a large gathering. Mr W. J. Stuart, chairman of the Governing Board, speaking on behalf of the older members of the medical school, said that Dr Orr began to teach there in 1913 and became dean in 1924, an almost whole-time job and one without any financial inducement. He managed the school with the most conspicuous success and had been a guide, guardian, servant, and benefactor. Mr D. S. Griffith, president of the Students' Representative Council, spoke on behalf of the students. Dr Orr, in his speech of thanks, said he wished the balance of the amount collected to be devoted to an annual prize for the students, and Sir John Fraser, Principal of the University, in accepting custody of the money for the Orr Prize, described Dr John Orr as one to whom the Medical School of Edinburgh owed a very great debt.

No. 9

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland. (d) Eire (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

* A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1946					1945 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ 5 imported cases.

EPIDEMIOLOGICAL NOTES

Maternal Mortality

Recent returns have shown that maternal mortality, for the country generally, has reached the lowest level yet recorded. The national standard of nutrition has been cited as the principal reason for this fall. In view of the publicity this death rate has received, an examination of the individual causes of death under this heading may be helpful in attempting to establish the reason for the decrease. The death rates per 1,000 total births (live and stillbirths) during the past ten years are tabulated below:

Cause of Death Ascribed to Pregnancy and Childbearing (Excluding Abortion): 1940 Classification

International List No	Cause of Death	1935	1936	1937	1938	1939	1940	1941	1942	1943	1944
142	Ectopic gestation	0.13	0.11	0.12	0.12	0.10	0.12	0.10	0.12	0.08	0.06
143	Haemorrhage of pregnancy	0.09	0.08	0.07	0.07	0.05	0.05	0.06	0.03	0.03	0.02
144	Toxaemia of pregnancy	0.20	0.23	0.24	0.21	0.27	0.21	0.22	0.17	0.14	0.10
145	Other accidents and diseases of pregnancy	0.05	0.06	0.06	0.05	0.04	0.02	0.03	0.02	0.04	0.04
146	Haemorrhage of childbirth, etc.	0.38	0.40	0.41	0.42	0.41	0.32	0.38	0.31	0.27	0.27
147	Infection during childbirth and the puerperium	1.34	1.18	0.79	0.70	0.62	0.54	0.47	0.42	0.39	0.28

149	Other accidents of childbirth	0.55	0.46	0.46	0.56	0.54	0.46	0.50	0.47	0.48	0.40
150	Other conditions of childbirth	0.09	0.09	0.08	0.06	0.05	0.03	0.04	0.03	0.03	0.03
142-150	Maternal causes	3.41	3.19	2.79	2.70	2.55	2.18	2.22	2.01	1.84	1.53

With the exception of 1941 the death rate has declined steadily during the past ten years. The most notable feature of the table is the large reduction in mortality from sepsis; this rate fell by 1.06 per 1,000 during the ten years and contributed 56% of the total decrease of 1.88. The only cause of death for which the improvement has appeared in the last few years is toxæmia of pregnancy, which has declined from 0.22 in 1941 to 0.10 in 1944. A factor that may affect any comparison of recent years with the pre-war years is the difference in average age at confinement. Data are not yet available on this point, but the marriage boom during the war resulted in a lower average age at marriage and possibly a lower age at first confinement.

Discussion of Table

The decreased incidence of pneumonia was general throughout the country, the largest fall being Durham 42. The decline in scarlet fever was mainly confined to Lancashire 40 and London 30. The local trend of the largest falls were Lancashire 73, and Yorkshire West Riding 43, and the greatest increase was Essex 42. The largest variations in the returns of diphtheria were decreases in Lancashire 14, and Monmouthshire 10. A fall in the notifications of measles was recorded in Lancashire 64, and in Norfolk 52, and an increase in Durham 48.

All the 23 cases of paratyphoid fever occurred in the village of Wootton, Newport M.B., Isle of Wight. The outbreak has been traced to infected milk, and the majority of the cases were among children. Dysentery continues to be widespread, and the principal returns were Lancashire 38, Leicestershire 32, Northumberland 27, Worcestershire 26, Warwickshire 25, London 24, Staffordshire 18, Gloucestershire 17, Surrey 14, Glamorganshire 13, Northamptonshire 12, Yorkshire West Riding 11, Cambridgeshire 10. No further case of dysentery has been reported from the outbreak in Hertfordshire, Bushey U.D., where 74 cases were recorded last week.

In Scotland infectious diseases were less prevalent. The only rises were scarlet fever 14, and dysentery 13. A diminished incidence was recorded for measles 101, whooping-cough 29, acute primary pneumonia 26, and diphtheria 20.

In Eire the notifications of diphtheria increased by 20, and of diarrhoea and enteritis by 11. In Dublin C.B., where the notifications have steadily increased during the past two weeks, 42 cases of diarrhoea and enteritis were recorded.

Week Ending March 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,137, whooping-cough 1,843, diphtheria 477, measles 1,672, acute pneumonia 849, cerebrospinal fever 45, dysentery 295, paratyphoid 16, typhoid 5. There were 112 deaths from influenza in the large towns.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology* Western, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Western*, London. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Western*, London.

ANY QUESTIONS?

Premature Ejaculation

Q.—I have heard of "local electrical treatment" for premature ejaculation. Can you give details of this or any other treatment?

A.—Premature ejaculation is often considered to show an excessive "keenness" on the part of the man. This is not the case. Premature ejaculation is due not so much to an excess of sexuality as to an inhibition against it. It is of the same nature as impotence—a means of avoiding intercourse. This may be due to some present-day cause, such as fear of getting a baby, but most commonly it arises from more deep-seated conditions—an unconscious fear of sex (though not a conscious one); a sense of guilt about sex which will not permit complete intercourse; an unconscious resentment against the female; or a narcissism, which seeks the pleasure without sharing it. The proper treatment is to discover and eradicate the cause, which can usually be done by an expert medical psychologist. In young married people the condition usually rights itself as confidence is gained. It is therefore important that the partners should try not to worry about it.

I have no experience of electrical treatment, but would suspect that, if it is successful, it is so on account of its suggestive effect. In fact this condition used often to be cured by suggestion treatment, which, though now little practised, may be permanent in its effects, in that, once a satisfactory result has taken place, everything goes well thereafter.

Thrombophlebitis Migrans

Q.—A male aged 40 has been having pain in his calf for four months. Two months ago he had severe pleuritic pain with slight haemoptysis. One month ago he had a thrombosis of the right femoral vein with oedema of the leg. During attacks his temperature is 100° F.; E.S.R. 20 mm. (Westergren). Sputum, x-ray, blood examination, W.R., etc., negative. Is the diagnosis thrombophlebitis migrans? What are the prognosis and the treatment?

A.—The sequence of events in this case is diagnostic of thrombophlebitis migrans. Even if the pulmonary episode is regarded as an embolic consequence of an earlier thrombophlebitis of the leg, there is still the ensuing right femoral thrombophlebitis to be taken into account. Fever and leucocytosis with increased E.S.R. are characteristic of this disease, and the negative results of the investigations mentioned are consistent with the diagnosis.

In general there is no obvious infective cause, but in some cases there are found foci of sepsis from which bacteraemia could arise. Blood cultures are negative. The ultimate prognosis is good, although occasionally venous thrombosis in the vessels of the brain, heart, or abdomen causes serious and sometimes problematic illnesses. The successive thromboses occur at intervals over a period ranging from two or three months to four or five years. At any time the illness may come to an end, no further phlebitis developing.

In the first place treatment is directed to the removal of any obvious cause such as dental sepsis. Symptomatic measures have to be adopted during the "thrombotic episodes." An augmented fluid intake and the administration of citrates should help to prevent further thromboses. The anticoagulant "dicoumarol" has

been used in the treatment of thrombophlebitis; in doses of 100 mg. thrice daily by mouth it is claimed to reduce the pain and oedema of the affected part. This drug is still under trial, and its use must be controlled by daily estimations of plasma prothrombin.

Incidence of Anaemia

Q.—Anaemia is now prevalent in this and other countries. When I was a student, at the beginning of the century, students' blood taken and examined for instructional purposes in the physiological laboratory never, for practical purposes, revealed anaemia. Would you agree that there was no generalized tendency to anaemia during the first half-dozen years of this century, but that from then on there was?

A.—There is no evidence that anaemia is more common in students to-day than formerly. The figures given for male students in the M.R.C. Special Report No. 252 on haemoglobin levels in 1943 are eminently satisfactory, as are those for women students in the Provinces (Higgins *et al.*, *Brit. J. Industr. Med.*, 1945, 2, 74). Figures for women students in the London area are less satisfactory, and there may have been some deterioration in them as a result of the dislocation of war and inadequate taking up of rations. For the population of the country as a whole there are few past figures to compare with modern surveys, but such as are available indicate that anaemia is actually less prevalent than it was. Perhaps the most convincing evidence of this is the decline in chlorosis. As shown by J. M. H. Campbell (*Gay's Hosp. Rep.*, 1923, 73, 247), there was a steady decline in the number of cases of chlorosis from 1903 to 1918. Campbell attributed this to improved conditions of factory life and domestic service, and there is no doubt that by and large this improvement has continued and, indeed, has been accelerated by the second great war.

Rh Factor and Mongolism

Q.—A young officer recently consulted me because his wife had given birth to a mongolian idiot, which had died after five days. They have one normal child aged 3. A doctor said that the child had died "because of the Rh factor." What is the Rh factor, expressed in words a layman would understand, and is there any connexion between this factor and mongolian idiocy?

A.—There is no connexion between the Rh factor and mongolism; the appearance of erythroblastosis in a mongol baby would be fortuitous. It seems strange, however, that a diagnosis of mongolism could have been made as early as the fifth day of life. Might not the condition have been kernicterus, discussed in a leading article in this *Journal* (Aug. 11, 1945, p. 188), in which the brain is damaged by the jaundice?

The "Rh factor" is now known to depend upon a complex of antigens borne in the red cells. Antibodies capable of agglutinating red cells carrying the corresponding antigens do not occur naturally; but they may develop in one of two ways in the serum of individuals not carrying those particular antigens: (1) by the transfusion of red cells containing an antigen into the circulation of a person lacking it; or (2) the antigen from a foetus may pass into the mother's circulation, and if she lacks it she may develop the corresponding antibody. This in turn passes back and agglutinates the foetal cells, so giving rise to erythroblastosis foetalis.

It has been found that one particular antigen belonging to the Rh complex, called "D" in the newest and simplest terminology, is much more important from the practical point of view than the rest. The great majority of cases of erythroblastosis arise in infants who possess D, having inherited it from their fathers, but whose mothers lack it. Anti-D develops in the mother's serum and agglutinates the infant's red cells. For practical purposes the presence or absence of D can be equated to the Rh-positive and Rh-negative categories of the original Rh story. In 10% of all pregnancies there is the combination of an Rh-negative mother and an Rh-positive child—i.e., the former lacks and the latter has the antigen D. In perhaps 5% of such instances anti-D develops in the mother's serum, giving rise to erythroblastosis foetalis. This will rarely, if ever, happen with a first child, unless the mother has previously been sensitized by blood transfusion. Apart from transfusion, the danger arises with the second or a subsequent child. Once the mother has been sensitized the risk in subsequent pregnancies is very great.

It must be noted, however, that an Rh-positive husband may carry the gene producing D upon both chromosomes of the pair concerned or upon one only. If upon both all children will carry D; if upon only one chromosome half his children will carry it. A child who does not carry D cannot, of course, have its cells agglutinated, even if the mother has developed anti-D, and so will escape.

If the death in the family mentioned in the question was due to erythroblastosis foetalis, it will be found that the mother lacks D, while the father and the first child possess it. The mother was, of course, sensitized during the first pregnancy, and anti-D may be demonstrable in her serum.

It is possible to distinguish (with little exception) whether the father carries the double or the single dose of D. If the double dose, the risks attaching to another pregnancy are great, and preparation should be made for transfusion with Rh-negative blood immediately after birth. If the father possesses the single dose of D only, the next child has a 50% chance of escaping altogether; and it may prove possible to determine which gene the child has inherited by checking the anti-D titre of the mother's blood at intervals during the pregnancy.

As the couple are young and may well wish to have more children, it would be a good plan to carry out the investigations mentioned, together with any others necessary should the story prove more complicated than is usual.

Pseudo-hypertrophic Muscular Dystrophy

Q.—Is there any cure or beneficial treatment for pseudo-hypertrophic muscular atrophy?

A.—The only substance known to influence pseudo-hypertrophic muscular dystrophy is glycine, which needs to be given in doses of 25 to 30 g. a day for an adult. But in some cases the discontinuance of glycine results in rapid deterioration. C. N. Armstrong (*Newcastle med. J.*, 1938, 18, 143) advises that glycine should be given only to females, and then only when the disease is rapidly progressive and the continuance of the treatment can be assured. Vitamin E, which has also been recommended, appears to be of no value.

Virilism and Schizophrenia

Q.—A woman of 29 with schizophrenia has marked virilism. Is insulin treatment of the schizophrenia contraindicated by the adrenal condition?

A.—No. Some degree of virilism in the female schizophrenic patient—e.g., increased hairiness—is normal to the psychosis. There is no satisfactory evidence that attempts at influencing adrenal output have any beneficial effect. The condition does not diminish the safety of insulin coma, or contraindicate its use.

Sunflower Seeds

Q.—Where I practise there is a widespread belief that sunflower seeds have a powerful therapeutic effect. The husk is removed, and fifty or sixty seeds make an effective dose. Lassitude is banished and a feeling of well-being follows. I have myself experienced the sensation after taking the seeds. They are also given to children to abort colds, and are said to be effective in three or four hours. Has *Helianthus* any place at all in the botanical pharmacopoeia?

A.—Sunflower seeds are certainly edible, and resemble the hazel-nut in taste. In Hungary, where the flowers are grown extensively to mark boundaries between gardens and fields, the seeds are used for feeding pigs and chickens. It is also considered a wholesome practice for children to pick and eat the seeds. Undoubtedly, if the seeds were larger and the husks could be more easily removed they would come into more general favour for human consumption. We have, however, been unable to trace any previous record indicating that the sunflower possesses special therapeutic properties. The prescribed dose of 60 seeds, moreover, failed in our experience to elicit any noticeable response, good or bad, in a single male adult volunteer of 10 st. (63.5 kg.) body weight. It must not be forgotten that characteristic physiological and psychological effects may be produced by the use of other common seeds, notably those of the poppy and hemp. There is nothing inherently improbable, therefore, in the claim that the ingestion of sunflower seeds should lead to a feeling of well-being and

to increased resistance to infection, although it would be surprising if any important therapeutic action should have escaped detection and general recognition for so long. The possibility that the seeds may have a beneficial action through the presence of some vitamin or other trace nutrient must be borne in mind, but this seems rather improbable in view of the very small dose of seeds which is prescribed, and the promptness of the alleged response.

Penicillin in Beeswax and Peanut Oil

Q.—Twice recently in "Any Questions?" I have seen references to penicillin in beeswax and peanut oil. What are the formula, mode of sterilization, and dosage?

A.—This method of administering penicillin, originally devised by Romansky and Rittman (for whose latest publication on the subject see *New Engl. J. Med.*, 1945, 233, 577), has undergone various improvements. The preparation now in vogue in the U.S.A. consists of peanut oil containing 4.8% beeswax, in which calcium penicillin is suspended to give a concentration of 300,000 units per ml. To achieve this concentration and the better results which it is said to give, penicillin of a high degree of purity is required (about 1,000 units per mg.). The purity and the anhydrous quality of the peanut oil are also important, and mechanical means are now employed for suspending the penicillin in it. This is therefore not a material the preparation of which can be lightly undertaken; it is a job for the factory rather than the pharmacist.

The only advantage of this method of administration is that fewer injections are required—in the treatment of gonorrhoea only one. On the other hand it is wasteful, the dose given being considerably larger than that required to secure the same effect by a series of injections of an ordinary solution. It is doubtful whether the penicillin supply position in this country justifies its extended use for the mere sake of convenience in treating ambulatory patients; but its employment in order to give severely ill patients an uninterrupted night's sleep is another matter.

Interstitial Mastitis

Q.—A single woman aged 46 had a subtotal hysterectomy two years ago. For two months she has complained of aching in the left breast; there is an area of typical interstitial mastitis involving the upper outer quadrant. What is the treatment?

A.—It is probable that the best "treatment" in this case would be masterly inactivity. At the age of 46 the patient is menopausal, although this is obscured by the previous hysterectomy. After the menopause such a condition is likely to be less troublesome so far as pain goes, though the physical change in the breast remains unaltered. In the writer's experience the pain is not severe in itself, but the psychological state of the patient, who is inclined to worry unduly about the condition and may even have a cancerphobia, exaggerates the intensity of the symptoms. Reassurance is an important part of the treatment, but if the pain is sufficiently severe to warrant treatment, then a mild irradiation with x rays or with low-intensity gamma rays from radium or mesothorium pads is usually successful. Synthetic oestrogens are sometimes used nowadays, but irradiation is probably more certain. Needless to say, such a case will be kept under periodic observation in view of the possibility of malignant change.

Pleural Effusion and Artificial Pneumothorax

Q.—Why do cases of pulmonary tuberculosis with an A.P. develop pleural effusions? Why is the effusion which accompanies an A.P. so persistent, while the effusion in a tuberculous patient who does not have an A.P. clears in two or three months?

A.—Pleural effusion developing in a tuberculous patient is due to an allergic reaction of the pleura to tubercle bacilli discharged into it from a subpleural focus. The severity of the pleural reaction depends upon the degree of hypersensitivity of the patient and the size of the infecting dose. Effusions are more common in tuberculous patients with a pneumothorax, presumably because in such a case the subpleural focus can rupture into a free pleural space, whereas if the pleural layers are in contact surface inflammation may cause the focus to become adherent before it reaches the stage of rupture. An

effusion in a pneumothorax does not, as a rule, take longer to resolve than an effusion in a comparable patient without a pneumothorax

Phenol in Oil

Q.—Almond oil the usual excipient for 5% phenol when used for injecting piles is in short supply. Can one substitute (a) oil of crocus or (b) liquid paraffin?

A.—Liquid paraffin is unsuitable, as mineral oils are sometimes not absorbed by the leucocytes and a granulomatous paraffinoma tumour may form. Oleum arachidis is used, but sometimes it produces systemic upsets—giddiness, pyrexia, etc. It will quickly be displaced by almond oil when this becomes available again.

Treatment of Malarial Recurrences

Q.—What is the best method of treating recurrences of (a) M.T. and (b) B.T. malaria?

A.—Clinical manifestations of malaria can be controlled within a few days by either quinine or mepacrine. Relapses of benign tertian malaria may occur after either drug, but mepacrine will, if continued for two to three weeks after the acute attack has been suppressed, completely eradicate malignant tertian infection. Relapses of benign tertian malaria may be prevented by paludrine, but the drug is not ordinarily available. Pamaquin, although not influencing the relapse rate of malignant tertian infection, appears to reduce that of benign tertian malaria. As the blood level of mepacrine is built up but slowly it is advisable with this drug to use initial "loading" doses. With these facts in mind the following practical scheme may be laid down:

Malignant Tertian Malaria.—Mepacrine 0.3 g. after food thrice on the first day, 0.2 g. after food thrice on the second day and 0.1 g. after food thrice daily for a further five days, this course should suppress the acute attack. To eradicate the infection the drug should be continued without interruption for a further three weeks in a daily dose of 0.1 g.

Benign Tertian Malaria.—Mepacrine for one week, in the dosage indicated above for the first week's treatment of malignant tertian infections—or quinine gr 10 (0.65 g.) thrice daily for a week—with, in addition, pamaquin 0.01 g. thrice daily after food. Some prefer to give the pamaquin after the course of mepacrine is finished, lest these two drugs together prove too toxic, but they can usually be given simultaneously. There seems little to be gained by prolonged treatment of benign tertian infections, and reliance must be placed on treating each relapse as it appears. Any concomitant disease or infection should be dealt with, and the patient's general health and nutrition should be maintained at the highest level.

If, particularly in malignant tertian infections, there is any fear that the patient may not be absorbing the drugs given by mouth—if he is gravely ill, has persistent vomiting, severe headache, delirium, or any sign suggesting cerebral involvement—it is essential that the infection be controlled with the utmost rapidity. In such cases treatment should be initiated by parenteral administration of quinine dihydrochloride 5 to 10 gr (0.32 to 0.65 g.) or mepacrine methanesulphonate 0.3 g. Usually one or two injections suffice to control the condition that made parenteral therapy necessary, after which the treatment may be continued by mouth, as already indicated.

INCOME TAX

Local Medical Society

"LAMBDA" explains that a considerable sum of money has been left to a local medical society, and asks whether, having regard to the objects of the society as set out in its printed rules and to the fact that "any surplus income" is given to medical charities, the income which the society will derive from the bequest will be liable to income tax.

* In order to claim exemption it must be shown that the interest forms part of the income of "a body of persons or trust established for charitable purposes only" and that the income has been so applied (Income Tax Act, 1918, Sec. 37). A perusal of the society's rules suggests that the main purpose of the society is the promotion of the interests of a group of individuals rather than the advancement of those public interests which might bring the purposes within the definition of a "charity." This is, however, a subject on which it is dangerous to be dogmatic, and "Lambda"

may be well advised to put his case to the Chief Inspector of Taxes, Marine Hotel, Llandudno. (Presumably a specific "trust" has been created by the deceased's will, the point in doubt being whether the purposes of that trust are "charitable.")

Liability after Demobilization

J P has been demobilized and will receive Army pay to April 24. He proposes to enter a partnership after a preliminary assistantship of three months. How will his liability to tax be dealt with?

* During his assistantship J P will come under the "pay as you earn" system and tax will be deductible from the payments due from his employers. For the period during which he is a partner the liability will fall under Schedule D—i.e., he will be liable to account to the other partners for his share of the tax payable by the firm in January and July, 1947. If, as is assumed to be the case, a car is necessary for the performance of his duties as an assistant and is being purchased before April 5, 1946, J P can claim to deduct from his civil earnings in 1945-6 20% of the cost as an "initial allowance" in addition to the percentage allowance for wear and tear for the period from the date of purchase to April 5, 1946. A visit to the office of the local inspector of taxes seems advisable in the somewhat complicated circumstances.

Employment after Demobilization

J B is a salaried assistant and inquires how the authorities arrive at the figures on which he is being taxed.

* The amount of tax payable is determined by two factors: (a) what allowances and reliefs the taxpayer is entitled to claim, and (b) the amount of the income. As regards the former no doubt J B has made the necessary claims while in the Army, and the local taxing authorities may have been informed of any allowances due from civil earnings, as regards (b) tax is deductible from the earnings of employment by the employer, who, of course, knows the amount payable. After the end of the financial year the employer sends to the tax office particulars of the pay and tax deducted, and that office can then make an assessment for the past year. The address of the tax office can be ascertained from the employer, and, as J B suggests a discussion with the income tax employer's officer there will no doubt be helpful.

Cost of Further Medical Studies

T W has recently been released from the Forces and is engaged on revision and extension of his medical studies with a view to "getting a higher degree and to earning more money." Are the expenses so incurred, including travelling to and from his residence, allowable?

* It is not clear what are the taxable earnings from which T W seeks to deduct these expenses, but in so far as they are incurred to improve his professional knowledge and skill the expenses represent an outlay of capital and cannot be allowed for income tax purposes. Normal current subscriptions would be allowable if set against general earnings assessable under Schedule D, if, however, T W's earnings arise from a definite employment and are therefore assessable under Schedule E they would be allowable only if the employer requires him to be a member of the society or association in question.

Residence in Hospital

W P is medical superintendent of a hospital. His quarters are rent free. The net rental value is assessed at £30 and W P is charged tax thereon. Is this correct?

* We presume that the net rental value is at least £30. The legal position is that the Schedule A assessment on the hospital is exempted from tax, but subject to the retention as liable to tax of the value of any residential portion of the premises occupied by an individual having a total income of £160 or more. The tax on W P's quarters is therefore properly due—whether it should be borne by W P or the hospital authority is a matter to be settled by themselves.

Pensioner Living Abroad

"INNOMINATE" will shortly be in receipt of a pension, and intends then to live abroad. Will that affect the allowances he can claim, and will income arising abroad be liable to United Kingdom income tax?

* If he definitely ceases to be a British resident "Innominate," as a British subject residing abroad (whether within or outside the Empire), will be entitled to a proportion of the allowances in the ratio of his British (liable) income to his total income (liable and not liable). If, for instance, he begins to draw his pension as from, say, Oct. 1, 1946, and ceases to be a British resident before April 6, 1947, then for 1946-7 he will be liable on all his income and entitled to the full allowances, but for 1947-8 he will not be liable on income arising abroad but will be entitled to only a proportion of the allowances.

LETTERS, NOTES, ETC.

Treating Minors for V.D.

Dr. AIDAN REDMOND (London, S.W.10) writes: As a regular reader of "Any Questions?" I cannot allow to go unchallenged the heresy propounded in the answer to "Treating Minors for V.D." (Feb. 9, p. 226), that "defaulting nowadays is of less importance from the public health point of view than formerly, since even one injection of penicillin usually rapidly renders the patient non-contagious." This dogma of abortive cure leading to non-infectiousness by a single injection of penicillin reveals a tragic ignorance of the management of venereal diseases by modern or any methods, and such speculation savours more of wishful thinking than of any knowledge of the known and unknown factors of penicillin therapy in V.D. If venereal disease is treated on your assumption, in all probability we shall soon—if adequate treatment and follow-up are not demanded by the public health authorities—have a situation as uncontrolled as in the sulphonamide era. In any case the mere abolishing of infectiousness is a long way from solving the whole problem of venereal disease transmission, and the "persuasion and tact" you also suggest are as proven failures as the wartime outbursts of educational fervour by the Ministry of Health and Regulation 33B. Venereal disease is a disease of youth, so there will always be defaulters until a uniform policy—including compulsion, quarantine, and notification—for all cases is adopted and penicillin given in adequate therapeutic doses for the most controllable and treatable of all the infectious diseases.

Nicotinic Acid in Coronary Disease

Dr. A. HENRY GREGSON (Stamford) writes: With regard to the "contradictory reports" on nicotinic acid in coronary diseases (Feb. 9, p. 226) 300 mg. per diem orally with pot. iod. 10 gr. (0.65 g.) per diem and deep slow breathing using the accessory muscles of respiration will give a high proportion of relief, and even cure, of symptoms (I have seen 2-year "cures"—a lot for one practice). But once glycerin trinitrate has been used, one must increase the B₃ and reduce one's hopes in proportion to the length of time comfort has come before cure.

Home Remedies

Dr. DENIS F. MCCARTHY, medical officer of health, County Mayo, writes from Castlebar: It is with interest that I read of the various treatments given in "The Poor Man's Physician" in the *Journal* of Jan. 26 (p. 142). I was particularly interested in the "pap of the halse." About four years ago I had a married female patient who had extensive bilateral pulmonary tuberculosis with involvement of the larynx, with consequent hoarseness almost extending to aphonia (she had refused sanatorium treatment). One dispensary day her father attended and said that she was "not so well," and I said that I would visit her. To get to the house, which was in a very remote part of the county, one has to cross the sea-shore at low tide to reach a by-road, finally leaving this to drive for about a mile over a boulder-strewn beach. The woman was up and had her head swathed in cloths. Her mother informed me that because of her hoarseness they had called in Mr. — "the wise man." He had informed them that "the tit of her throat" had fallen down but that he would lift it, and that then she would be all right. An egg was boiled for ten minutes and was then bound on to the crown of her head, where it was to remain for ten days. If this had happened four days previously. On investigation I found the egg *in situ* on her head. They were all pathetically convinced that this treatment would be rapidly efficacious—a confidence which was not borne out by the event, as she died not long after. I have heard of and encountered several most peculiar home remedies—one especially being dangerous—but I had never previously met this particular one. Could it, I wonder, be suggested that this treatment throws an interesting sidelight on racial characteristics, the "canny Scot" using half an egg, and the less thrifty Irishman using a whole one?

Exercises to Prevent Chilblains

Dr. R. KENNETH McALL writes from Edinburgh: During 3½ years' internment in China I tried out on patients with chilblains of the fingers exercises I had learnt from Chinese artists, which they use to keep their fingers subtle. In camp not only did more than 100 find it preventive, but others who came with advanced swollen, cracked fingers found it curative. One extreme example was a man whose fingers were extremely swollen and whose wedding-ring was deeply embedded. I sent him off to get a file from the P.W.D., at the same time blaming him for not following the exercises that I had advertised on the public health notice board. Thirty-six hours later he returned with no chilblains; he had cured himself with intensive exercise. It is just this. Take two small round objects, or, more simply, two walnuts and play with them in one hand, working out such games as never letting them bump, or working them around each finger in turn without the assistance of the other hand. Whenever we were walking we played with them in the pocket, or at any idle moment or if writing played with them in

the left hand. It was a common sound to hear the rattle of these nuts in the camp. Our rooms were sometimes below freezing; there was no heating, food was very low, and clothing a difficulty.

Coccygodynia or Proctalgia?

Dr. S. LEWIN (Birmingham) writes: Twelve years ago a male patient, 38 years old, was seen by me with symptoms identical with those described by Dr. T. Astley Cooper (Feb. 2, p. 192). Rectal examination showed piles of the first degree. The symptoms persisted and could be relieved only by 1/8 gr. (8 mg.) morphine suppository on retiring. Ten months later a small anal fissure was found on the posterior margin. On surgical treatment for this condition the symptoms completely disappeared, and so far there has been no recurrence.

Suturing the Abdominal Wall

"G.P." writes: After performing a number of surgical and gynaecological operations for twenty-five years, and coming across only one instance of a ruptured wound (in a case of ruptured duodenal ulcer in which all sutures were removed by mistake after nine days!), I think that one of your recent correspondents (Jan. 12, p. 66) has been singularly unfortunate. I admire his frankness in admitting that in six months two hysterectomies, a perforation, a hemicolectomy, a choledochotomy, and a rectal prolapse all went wrong so far as the suturing of the abdominal wall was concerned. But does it not appear more likely that undue haste, if not a fault in the very simple technique of stitching, has something to do with it? The surgeon with a list of eight or ten operations, and an eye on the clock, acts not like an expert paperhanger but a billposter. Most surgeons in my experience are careful so far as they are operating on the viscera, but when it comes to stitching up the abdominal wall they either leave it to inexperienced assistants or do it themselves so hurriedly that when the time for removing sutures comes the tragic results are laid bare for all to see, and the cough and the anaesthetic get the blame.

Applying for a Hospital Post

Mr. W. R. WELPLY, F.R.C.S. (Southport), writes: I heartily endorse the remarks made by Mr. A. Wallis Kendall (Jan. 26, p. 154) about the numbers of copies of applications required by certain hospitals from candidates for the various posts advertised in your and other journals. I wish to stress that, at the present time, so many senior as well as junior hospital staff appointments are vacant that a very high percentage of those medical and surgical members of the profession who are working, or wish to work, in hospitals are now applying for the advertised vacancies. One cannot, therefore, chance applying for one or two posts only, but has perforce to apply for ten, twenty, or maybe thirty, as the selections for these vacancies are almost all being made in April, May, or June. If one relied on one or two separate applications only and failed to be selected one would have lost the opportunity of applying for all those others being appointed the same month. As so many require multiple copies of applications and also of testimonials, it becomes well-nigh impossible to submit typewritten applications, and the whole thing has to be printed. Printing takes time, and it becomes necessary to order enough copies in advance to cover all the posts for which one intends to apply for the next six months at least. Consequently anything from 250 to 500 copies of application and testimonials must be purchased, and as the more "elegant the production," as Mr. Wallis Kendall points out, is generally considered to favour a candidate, it becomes necessary to demand the highest class of paper and workmanship from the printer. Few can achieve this at less than £15 15s., which is equivalent to a whole month's salary (considering income tax) for many of those applying. Many a young man cannot afford this and his chances are jeopardized. Certain teaching schools, such as Liverpool, require one copy of application only; why, then, must some of the London teaching hospitals demand sixty? Probably merely because it has always been done before: but times have changed. The B.M.A. stepped in and advised hospitals to wait four months from the date of advertising to the date upon which applications closed, and partly through this the present position has arisen whereby a large number of posts have all been advertised together. Surely the B.M.A. should now step in once more to ease the burden of the younger "specialists" as well as easing the position due to the paper shortage by advising hospitals to ask for a reasonable number of copies of applications and testimonials—say, six rather than sixty. It is not yet too late to make this move.

University Election

Prof. H. E. ROAF (Liverpool) writes: Some time ago I promised to support the candidature of Mrs. Stocks for the Parliamentary vacancy caused by the death of Miss Eleanor Rathbone. When I received Mrs. Stocks's election address I was appalled to see her views on the proposed health service. I have written to Mrs. Stocks withdrawing my support, and I want to state publicly that I can no longer support her candidature because of her attitude to an unknown proposal.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 30 1946

BRITISH MEDICAL ASSOCIATION AND THE NATIONAL HEALTH SERVICE BILL

We print below a copy of the Government White Paper, in which are described the provisions of the National Health Service Bill.

The White Paper is followed by a report submitted for the information of the profession by the Council of the British Medical Association.

This falls into two parts: A, a statement of the principles adopted by the Negotiating Committee with explanatory paragraphs; B, a report of the Council of the British Medical Association on the Bill to be submitted to a Special Representative Meeting to be held on May 1 and 2, 1946. All members of the profession, members and non-members of the Association alike, are urged to give this document the most careful study and to attend the meetings of the profession to be called in every area in the next few weeks.

NATIONAL HEALTH SERVICE BILL

SUMMARY OF THE PROPOSED NEW SERVICE*

[This White Paper contains a general description of the proposed health service. It is intended only as a factual summary, and, being only a general summary, cannot always be in precise terms.]

INTRODUCTORY

1. The Bill provides for the establishment of a comprehensive health service in England and Wales. A further Bill to provide for Scotland will be introduced later.

2. The Bill does not deal in detail with everything involved in the service. It deals with the main structure. Within that structure, further provision will be made by statutory regulations—on lines which the Bill lays down and subject always to the control of Parliament.

Scope of the Service

3. The Bill provides for the following kinds of health services:

(i) Hospital and specialist services—i.e., all forms of general and special hospital provision, including mental hospitals, together with sanatoria, maternity accommodation, treatment during convalescence, medical rehabilitation and other institutional treatment. These cover in-patient and out-patient services, the latter including clinics and dispensaries operated as part of any specialist service. The advice and services of specialists of all kinds are also to be made available, where necessary, at Health Centres and in the patient's home.

(ii) Health Centres and general practitioner services—i.e., general personal health care by doctors and dentists whom the patient chooses. These personal practitioner

services are to be available both from new publicly equipped Health Centres and also from the practitioners' own surgeries.

(iii) Various supplementary services—including midwifery, maternity and child welfare, health visiting, home nursing, a priority dental service for children and expectant and nursing mothers, domestic help where needed on health grounds, vaccination and immunization against infectious diseases, additional special care and after-care in cases of illness, ambulance services, blood transfusion and laboratory services. (Special school health services are already provided for in the Education Act of 1944.)

(iv) The provision of spectacles, dentures, and other appliances, together with drugs and medicines—at hospitals, Health Centres, clinics, pharmacists' shops, and elsewhere, as may be appropriate.

Availability of the Service

4. All the service, or any part of it, is to be available to everyone in England and Wales. The Bill imposes no limitations on availability—e.g., limitations based on financial means, age, sex, employment or vocation, area of residence, or insurance qualification.

5. The last is important. If the National Insurance Bill now before Parliament is passed into law, almost everyone will become compulsorily insurable, and after payment of the appropriate contributions will become entitled to the various cash benefits—including sickness and maternity benefits—for which that Bill provides. A proportion of their contributions will be used to help to finance the health services under the present Bill, but the various health service benefits under the present Bill are not made conditional

* London, H.M. Stationery Office, Cmd. 6761, 3d. net.

upon any insurance qualification or the proof of having paid contributions. There are no waiting or qualifying periods.

6. The service is to be available from a date to be declared by Order in Council under the Bill, and it is hoped that this will be at the beginning of the year 1948.

The Service to be Free of Fees or Charges

7. The health service is to be financed partly from the Exchequer, partly from local rates, partly from the help (mentioned above) which part of the National Insurance contributions will give. There are to be no fees or charges to the patient, with the following exceptions:

(i) There will be some charges (to be prescribed later by regulations) for the renewal or repair of spectacles, dentures, and other appliances, where this is made necessary through negligence in the care of the articles provided.

(ii) There will be charges (taking into account ability to pay) for the provision of domestic help under the Bill and for certain goods or articles (e.g., supplementary foods, blankets, etc.) which may be provided in connexion with maternity and child welfare or the special care or after-care of the sick.

(iii) It will be open to people if they wish, in certain cases, to pay for additional amenities within the arrangements of the service—e.g., to pay extra for articles or appliances of higher cost than those normally made available, or to pay charges for private rooms in hospitals (which they will nevertheless be able to obtain free where privacy is medically necessary).

General Organization of the Service

8. The Bill places a general duty upon the Minister of Health to promote a comprehensive health service for the improvement of the physical and mental health of the people of England and Wales, and for the prevention, diagnosis, and treatment of illness. To bring physical and mental health closer together in a single service, it transfers to the Minister the present administrative functions of the Board of Control in regard to mental health (the Board retaining only its quasi-judicial functions connected with the liberty of the subject).

9. The Bill proposes that the Minister shall discharge his general responsibility through three main channels:

(a) For parts of the service to be organized on a new national or regional basis—i.e., hospital and specialist services, blood transfusion, and bacteriological laboratories for the control of epidemics—the Minister is to assume direct responsibility; but he is to entrust the actual administration of the hospital and specialist services to new regional and local bodies established under the Bill. These bodies are to act on his behalf in suitable areas to be prescribed by him, and they are to include people of practical experience and local knowledge and some with professional qualifications. Special provision is made for hospitals which are the centres of medical and dental teaching.

(b) For parts of the service to be organized as a function of local government—i.e., the provision of new Health Centre premises and a variety of local domiciliary and clinic services—direct responsibility is put upon the major local authorities, the county and county borough councils. They will stand in their ordinary constitutional relationship with the central Ministry, but their general arrangements for these local services are made subject to the Minister's approval.

(c) For the personal practitioner services both in the Health Centres and outside—i.e., the family doctor and dentist and the pharmacist—new local executive machinery is created, in the form of local Executive Councils. One half of the members of each of these Councils will consist of people nominated by the major local authorities and by the Minister, and the other half of people nominated by the local professional practitioners concerned. There will normally be an Executive Council for each of the major local authorities' areas, and they will work within national regulations made by the Minister.

10. By the Minister's side, to provide him with professional and technical guidance, there is to be set up a Central Health Services Council. This will include people chosen from all the main fields of experience within the service—with various standing committees of experts on particular subjects, medical, dental, nursing, and others.

11. Each of these branches of the new organization is described in more detail in the rest of this paper.

HOSPITAL AND SPECIALIST SERVICE

12. This part of the service covers hospital and consultant services of all kinds, including general and special hospitals, maternity accommodation, tuberculosis sanatoria, infectious diseases units, provision for the chronic sick, mental hospitals and mental deficiency institutions, accommodation for convalescent treatment and medical rehabilitation, and all forms of specialized treatment—e.g., orthopaedics, cancer, neurosurgery, plastic surgery, paediatrics, gynaecology, ophthalmic services, ear-nose-and-throat treatment, and others.

13. It is made the Minister's general duty to provide these physical and mental hospital services, but he is to entrust their administration to Regional Hospital Boards, together with separate Boards of Governors for the teaching hospitals, in manner to be described later.

14. The existing premises and equipment of voluntary and public hospitals are transferred to the Minister under the Bill, and he is empowered also to acquire by purchase—if necessary—other hospitals and their equipment which may be required for the purposes of the new service. If in any particular case he is satisfied that the transfer of a hospital is not in fact necessary for the new service he can—with that institution's concurrence—except it from transfer. The general transfer of hospitals includes the present mental hospitals and mental deficiency institutions.

15. The endowments of voluntary teaching hospitals—defined in the Bill to mean, broadly, all their property other than buildings and their contents—will pass, not to the Minister, but directly to the new Boards of Governors, who are to be free to use them as they think best, but are required, so far as practicable, to see that the purposes for which they were previously usable are still observed.

16. The endowments of other voluntary hospitals are to pass to a new Hospital Endowment Fund which the Minister is to set up and administer in the following way. He is first to meet from the Fund, to such extent as may be settled by subsequent regulations, existing debts and liabilities attaching to the voluntary hospitals concerned. He is then to apportion the capital value of the Fund among the several Regional Hospital Boards and, as it were, to earmark to each a portion. The income of each portion will then pass automatically to each Board, and it will be free to use it as it wishes, within such general conditions as may be prescribed. Any Board will be able also at any time to draw on its portion of the capital for any purpose which the Minister approves.

17. The Boards—and the Boards of Governors of teaching hospitals—are fully able under the Bill to receive gifts or legacies, and to hold any property on trust, for any purposes connected with the hospital or health services.

18 The detailed arrangements affecting the new Hospital Endowment Fund, its apportionment and administration, are left to be settled by later statutory regulations

Hospital Administration

19 The Minister is to entrust the future administration of all the hospitals (other than teaching hospitals) to Regional Hospital Boards to be set up under the Bill for such hospital service regions of the country as he will prescribe—each region being such that its services can conveniently be associated with a university medical school. There will probably be between sixteen and twenty of these regions

20 Each Board will be composed of people chosen and appointed by the Minister for their individual suitability for the task, but before making the appointments the Minister is to consult any university with a medical school in the region, bodies representative of the medical profession, the local health authorities of the area, and others concerned, including initially, those with experience of the voluntary hospital system. The Boards are to include some members with experience of the mental health services

21 Each Board is required by the Bill to appoint, in accordance with a scheme approved by the Minister, local Hospital Management Committees, one for each large hospital or related group of hospitals forming a reasonably self-contained hospital service unit. Each of these Management Committees will contain members appointed after consulting the major local authorities in its area, the Executive Councils for the general practitioner services in its area, the senior medical and dental staff of the hospitals concerned, and others, including those with experience in voluntary hospitals

22 It is to be the duty of the Regional Boards within the scope of general regulations and such particular directions as the Minister may give, to undertake on his behalf the general administration of the hospital and specialist services in their regions. With the Minister, and in collaboration with the teaching hospitals, each Board will plan, and execute the plan for, a co-ordinated hospital and specialist service for its region

23 It is to be the duty of the Management Committees to carry out day-to-day management of the particular hospitals under their control—within such limits as are to be prescribed by the Minister. They are to be the local managing bodies on the spot, and they will, for example, appoint nursing and other general staff (appointing them as employees of the Regional Boards). They will be able, as required, to set up small house-committees for any individual hospitals within their care

24 It is the object that the Regional Boards, with their local Management Committees, shall enjoy a high degree of independence and autonomy within their own fields. Their use of existing voluntary hospital endowments has already been described. For the general financing of their hospital services, however, they will look to the Exchequer, and they will be given as much financial freedom—by a system of block annual budgets or otherwise—for local initiative and variety of enterprise as general principles of Exchequer responsibility make possible

Teaching Hospitals

25 Special arrangements are provided for teaching hospitals—that is, hospitals or groups of related hospitals which are designated by the Minister as providing the facilities for undergraduate or postgraduate clinical teaching. These will enable any hospital or group of hospitals to attain "teaching" status whether it is already a teaching hospital at the outset of the scheme or not

26 The general system of Regional Boards and Management Committees will not cover the teaching hospitals. The Minister is to constitute for each such hospital or group of hospitals its own separate Board of Governors, including members nominated by the university, the Regional Board for the area, and the senior staff of the hospital itself, and members appointed after consultation with the major local authorities and other organizations concerned including the previous governing bodies. The Board of Governors of a teaching hospital will be responsible generally for administering their hospital on the Minister's behalf

27. The financial arrangements in regard to exchequer their joint endowments of the teaching hospitals have been divided, described. For the general financing of their service, look to the Exchequer, and again the general object is to assure them all the financial freedom and autonomy of a unit which the general conception of a nationally reorganized and nationally financed service makes possible. In this case in addition it is intended to keep in the forefront of any arrangements the special position of these hospitals as the centres of clinical teaching and technical experiment and innovation

28 The fact that special administrative and financial arrangements may be made for teaching hospitals does not mean, however, that these hospitals are not to form an integral part of the hospital service as a whole. They will be joined with the Minister and the Regional Boards in the general planning and arrangement of the hospital services of each region, and the Regional Boards will be represented on their Boards of Governors

Medical and Dental Schools

29. Medical and dental schools are not to be transferred to the Minister or to the Board of Governors of the teaching hospital with which they are associated. No property which is held for the purposes of these schools is to be transferred. The schools will continue to be owned and administered, in London, by their own governing bodies and elsewhere by the governing bodies of the universities of which they form part, and the Bill provides for the transfer of any existing hospital property held for school purposes to these governing bodies

30 The Bill contains also a special provision relating to medical and dental schools, based on recommendations of the Interdepartmental Committee on Medical Schools (the Good enough Committee). Any medical or dental school of London University which is not yet a body corporate is required to take steps within six months of the passing of the Bill to become incorporated

Hospital Staffs

31 The staff of all hospitals in the service will be in the employment of the Regional Boards or Boards of Governors of teaching hospitals as the case may be. Specialists taking part in the service, whole-time or part-time, will be attached to the staff of hospitals. Part-time participation in the service will not debar the specialists from also continuing any private practice outside the service which individual patients may wish them to undertake

32 Special provision is to be made by regulations affecting the appointment of senior medical and dental staff employed on the staff of hospitals. In these cases the Regional Board or the Board of Governors, as the case may be, is to be required to advertise vacancies and to constitute an expert advisory appointments committee. The committee will draw up a list, from among the applicants, of those suitable by qualification and experience for the vacancy, and the person to be appointed will then be selected from that list by the Board

33 The Boards will determine the terms of engagement of any staff employed in the hospital service. The Minister, however, is empowered to make regulations governing the qualifications, conditions of service, and remuneration of any or all classes of hospital staff—as of the staff engaged in any other part of the health service. Before making regulations he will consult any appropriate organizations representing the staffs concerned, and it will be his intention—wherever appropriate—to use existing, or set up new, negotiating machinery to facilitate those consultations. Existing hospital officers employed on a paid whole-time basis are to be protected, either by being transferred to the new bodies or by compensation if they are not transferred or are re-employed on less favourable terms than before

"Pay-bed" Accommodation

34 Where there are single bedrooms or small wards in hospitals the Minister is empowered to make them available to patients who wish to buy greater privacy by paying the extra

urgently require it. Private

patients using the accommodation will pay their own specialists' fees, but the Bill enables the Minister to prescribe maximum fees which specialists may charge in these circumstances.

Other Centralized Services

36. The Minister is made directly responsible for the provision of two other services, both of them developed from services which have grown up during the war.

37. The first is a bacteriological service for the control of the spread of infectious diseases, including, in particular, the provision of laboratories. These will be operated—at least in the first instance—by the Medical Research Council on the Minister's behalf and their services can be made available to medical men and others who wish to make use of them.

38. The second is a blood transfusion service—for the collection of blood from volunteer donors, the provision of "blood banks" and blood products at hospitals, and of mobile transfusion teams which will be on call for hospitals not possessing facilities of their own and for specialists and general practitioners.

39. The Minister is also expressly empowered by the Bill to conduct research, and to give financial help to voluntary agencies conducting research, into any question relating to the prevention, diagnosis, or treatment of illness or mental defectiveness. Boards of Governors of teaching hospitals and Regional Boards are also empowered to conduct research.

GENERAL PRACTITIONER SERVICES

40. This part of the service covers the personal health services provided by general medical practitioners and dentists and the supply of drugs, medicines and appliances.

41. To arrange these services locally new bodies—to be called Executive Councils—are to be established in the area of each county and county borough. As already explained, each Council is to be so composed that one half of its members are professional—appointed by the local doctors, dentists, and chemists through their own representative committees in the area—while the other half of the members are to be appointed partly by the local county or county borough council (one-third of the Executive Council) and partly by the Minister (one-sixth). The Chairman will be appointed by the Minister. Single Executive Councils may sometimes be established for the areas of two or more local authorities.

Health Centres

42. A main feature of the personal practitioner services is to be the development of Health Centres. The object is that the Health Centre system, based on premises technically equipped and staffed at public cost, shall afford facilities both for the general medical and dental services (described immediately below) and also for many of the special clinic services of the local health authorities (described later), and sometimes also for outpost clinics of the hospital and specialist services (already described). Beside forming a base for these services—e.g., providing doctors with equipped and staffed consulting rooms in which to see their patients—the Centres will also be able to serve as bases for various activities in health education.

43. The Bill makes it the duty of the county and county borough councils to provide, equip, staff, and maintain the new Health Centres to the satisfaction of the Minister. The local authorities will directly administer such of their own local

clinic facilities as they may provide in the Centres. Doctors and dentists, however, who use the new Centres while participating in the general personal practitioner service will be in contract only with the new Executive Councils, and it will be for those Councils to arrange with the local authorities for the use of the Centres' facilities by those doctors and dentists. In the case, for instance, of doctors in the general practitioner service the Centres will, in effect, stand in place of the doctors' own surgeries, and the doctors' responsibilities to their patients on their personal lists—e.g., in visiting their patients' homes—and in general responsibility for their patients at all times—are not affected by whether a doctor practises from a Health Centre or not.

Family Doctor Service

44. All doctors are to be entitled to take part in the new arrangements in the areas where they are already practising when the scheme begins. Taking part will not debar them from also continuing to make private arrangements for treating such people as still wish to be treated outside the service instead of taking advantage of the new arrangements, provided that such persons are not on their lists as public patients or on the lists of their partners in a Health Centre. People will be free to choose their own doctor (including their present doctor) subject to the doctor's consenting and being in a position to undertake their care.

45. All doctors taking part in this part of the new service will be in contract with the Executive Council for the area in which they practise. The Executive Council will be required to draw up and publish lists of all general practitioners who wish to participate. People will then choose their doctor and each doctor will have his own list of the people whom he has agreed to attend. There will be machinery for allocating among the doctors concerned such people as wish to take advantage of the service but have not chosen a doctor for themselves or have been refused by the doctor chosen by them. The relationship of the doctor with any person on his list—i.e., his function under this part of the service—will then be similar to the ordinary relationship of doctor to patient as it is now known except that the doctor's remuneration will come from public funds and not directly from the patient.

46. The Bill itself does not determine the detailed terms and conditions for doctors joining in the service or the doctors' remuneration. These are left to be settled by regulations, and the necessary regulations will be made in consultation with the doctors' professional representatives. It is, however, the intention that remuneration should take the form of a combination of fixed part-salary and of capitation fees, the latter varying with the number of persons whose care is undertaken by each doctor and being so graduated as to diminish in scale as the total number of patients rises. Variations of the fixed part-salary will be possible so as to take account of different circumstance and experience and the differing conditions of practice in particular areas. It is intended also to institute, under power contained in the Bill, a contributory superannuation scheme for doctors taking part in the new arrangements.

47. Actual rates of remuneration for doctors can be determined, in consultation with the profession, only after the report has been received of the Spens Committee—a special committee set up, by agreement with the profession's representative and under the chairmanship of Sir Will Spens, with a membership half medical and half non-medical, to make an independent report on the appropriate range of remuneration for doctor taking part in a publicly organized service of this kind.

48. When the necessary regulations affecting terms of service and remuneration have been settled it will be for the Executive Councils to contract with the doctors on the lines thus prescribed.

Distribution of Medical Practices

49. To help in dealing with the needs of under-doctored areas it is intended, as already indicated, to adjust the scales of remuneration of doctors so as to provide additional inducement to practise in less attractive areas. In addition, a new body to be called the Medical Practices Committee, mainly professional in composition, is to be appointed under the Bill to regulate it

future the succession to old, or the opening of new, practices within the service.

50. To begin with, an appointed day will be fixed and all doctors then in practice will have the right to have their names included on the lists drawn up by the Executive Councils for the areas in which their existing practices are. After the appointed day any doctor who wishes either to join the public service for the first time or, if he is already in it, to go and practise in a new area will need to obtain the consent of the Medical Practices Committee. He will normally ask to have his name included in the list of the Executive Council for the area of his choice, and that Council will inform the Committee. The Committee may give consent either unconditionally or subject to a condition as to the general part of an Executive Council's area in which he practises. They will not be able to withhold consent on any ground except that there are already enough doctors practising in the public service in the area in question. If, when a practice becomes vacant in a particular area, there is more than one applicant for taking it over, the Committee will decide to which doctor the necessary consent is to be given. A doctor whose application to practise in a particular area is refused, or granted only subject to conditions, is given the right to appeal to the Minister.

51. Regulations governing all these arrangements will, among other things, require Executive Councils to report from time to time to the Medical Practices Committee on the number of doctors required to meet the needs of their areas and on the existence of vacant practices on their lists.

Sale and Purchase of Practices and Compensation

52. The above control of succession to, or opening of, practices will apply to all practices which are wholly or partly within the service. It will, therefore, make the sale of the goodwill of such practices inappropriate, and the Bill provides for the prohibition of the sale of such practices in future and for compensation to existing practitioners in respect of the consequent loss of selling values.

53. Doctors who join in the public service at the outset will be entitled to compensation in respect of loss incurred through being unable thereafter to sell their practices. In addition, any doctor who dies or retires from practice between the passing of the Act and the appointed day, and whose practice has not been sold in the meantime, will qualify for compensation. If he is compensated, his practice will be regarded as having come within the service at the appointed day.

54. The total amount of compensation to be made available to the profession under the Bill is a sum of £66 million for England and Wales and Scotland, and the appropriate proportion of this is authorized to be paid in England and Wales under the present Bill. Provision is made for the total sum to be reduced if the number of practitioners taking part in the service falls substantially short of the expected total.

55. Regulations will govern the detailed method of apportioning the global sum among the doctors entitled to compensation and the manner and times at which it is to be paid. It is intended that the settling of the apportionment of compensation among the individual doctors shall be left in the main to the profession itself, and the Minister will accept any reasonable proposals within the total sum. Normally compensation is to be payable on the retirement or death of a doctor, though payment at an earlier date will be arranged where hardship (e.g., through outstanding debts) would otherwise arise. In the meantime interest on the compensation due is to be paid each year to the doctor at the rate of 2½% per annum.

Doctors and the Health Centres

56. As and where the new Health Centres are developed existing doctors in the area will be able, if they wish, to use the consulting rooms and other facilities so provided in place of their present surgeries, so far as they are participating in the new service. Their doing so will not affect the general arrangements already described.

57. Any group of doctors joining in practice from a Health Centre, however, will be encouraged—wherever possible—to

enter into a partnership arrangement whereby their joint remuneration within the service is pooled and then divided among them on some agreed basis of apportionment.

Supply of Drugs, Medicines, and Appliances

58. Those who use the general practitioner service will be entitled to the supply, free of charge, of necessary drugs, medicines, and appliances. A charge will be made if appliances have to be prematurely repaired or replaced as a result of carelessness, and if the patient chooses to be supplied with more expensive appliances than those normally supplied he will be expected to meet the additional cost involved.

59. Every properly qualified pharmacist who wishes to join in the new service will have the right to do so. The Executive Council in each area is to draw up and publish a list of pharmacists who join in the service, and patients will be able to obtain their supplies on the prescription of their doctor either from the shops or other premises of a pharmacist or from any Health Centre where dispensing services are provided, as the patient chooses. Drugs, medicines, and appliances required for hospital purposes will be supplied as part of the hospital service.

60. Regulations, made in consultation with the professional organizations concerned, will govern the detailed terms and conditions, and rates of remuneration, on which pharmacists participate in the new arrangements.

Dental Service

61. The arrangements for dental services will be on rather a different basis from the family doctor service. Priority will be given to expectant mothers and young people. This is to be done through the local health authority's maternity and child welfare service (which the Bill expressly provides is to include dental care) and through the school health services under the Education Act, 1944. Outside the priority arrangements there will be a general dental service made available, but there will not at first be any guarantee that all people will be able to obtain full dental care without waiting. Any dentist who wishes to participate in the general dental service will have the right to do so, and the Executive Council in each area will draw up and publish a list of those who undertake to participate in the service.

62. The object will be to develop general dental services in the Health Centres, or corresponding Dental Centres, as much and as quickly as possible. In the Centres it is intended that dentists shall be able to participate either whole-time or part-time and shall be remunerated by appropriate salaries for the amount of time which they give to the new service. Outside the Centres it will be open to anyone to arrange with any dentist in his own surgery who agrees to undertake his or her dental care. The dentist will normally be able to start treatment without further reference, and subsequently to submit a claim for payment from public funds. For certain forms of treatment, however, the dentist will submit an estimate of what is required to a new professional body established by the Bill—the Dental Estimates Board. The Board will have branch offices in different parts of the country whose function it will be to approve dentists' estimates for treatment to be given or appliances to be supplied. Payment will be made to the dentist by the Executive Council in accordance with a prescribed scale of fees or, in some cases, on special estimates determined by the Dental Estimates Board.

63. The detailed terms and conditions, and rates of remuneration, on which dentists will participate in the service are not settled in the Bill itself, but—as with the doctors—are to be the subject of subsequent regulations made in consultation with the profession's representatives. The general range of remuneration is to be settled in the light of the findings of a committee established (by agreement with the profession) on lines similar to the Spens Committee on Doctors' Remuneration. Dentists taking part in the general dental service will not be debarred from treating under private arrangements anyone who does not wish to take advantage of the service.

64. When the appropriate regulations affecting remuneration and general conditions of participation in the service have been

settled, it will be for the Executive Council to contract with the dentists on the lines so prescribed.

Eye Services

65. The object is to secure that the care of the eyes, with sight-testing and the supply of spectacles, is carried out—as rapidly as resources allow—in special ophthalmic departments and clinics forming part of the hospital and specialist service. These clinics will be in the charge of specialist medical ophthalmologists, and in them the qualified sight-testing opticians will also play their proper professional part. Spectacles will be obtainable either at the clinics themselves or at the premises of dispensing opticians taking part in the service.

66. While this full eye clinic system is developing, however, a supplementary eye service is to be arranged by the Executive Councils in each area. Their arrangements are to be made with suitably qualified general medical practitioners, sight-testing opticians, and dispensing opticians who undertake the supply of spectacles. The whole of the arrangements are to be entrusted by each Executive Council to a special committee—an Ophthalmic Services Committee—which will draw up and publish lists of the medical practitioners and opticians who have the necessary qualifications and who wish to participate in the service, on the same lines as the lists of doctors and dentists. The patient will then have freedom of choice among the doctors and opticians on the lists.

67. As in the rest of the general practitioner services, the terms and conditions and rates of remuneration of those participating in the supplementary eye service, arranged by the special Committee of the Executive Council above, will be the subject of later regulations.

68. People will be entitled both to sight-testing and to the supply of spectacles, free of charge, either at the specialist ophthalmic clinics or through the supplementary scheme just described. The Bill provides, however, that as soon as the Minister is satisfied that adequate ophthalmic services are being provided in any area through the specialist clinic services he may wind up the supplementary service in that area.

Miscellaneous

69. A special Tribunal is to be set up to investigate cases where it is claimed—either by the Executive Councils or otherwise—that the continued inclusion of any doctor, chemist, dentist, or optician in the lists drawn up by the Executive Councils would be prejudicial to the efficiency of the service. The Tribunal will have a legal chairman appointed by the Lord Chancellor and will in each case include a member of the same profession as the person whose case is being investigated and one other—the latter two being appointed by the Minister. Where it is satisfied that the representations are justified, the Executive Council will be directed to remove from the list the name of the doctor, dentist, chemist, or optician, who is given the right to appeal to the Minister. Where the Tribunal so decides a similar direction can be applied to all lists in all areas, with the same right of appeal.

70. Provision is also made that where any doctor, dentist, chemist, or optician has already been disqualified from participation in the present National Health Insurance service, and the disqualification has not been removed, he shall not have the right to participate in the new service.

71. Where the Minister is satisfied, after inquiry, that the services provided by doctors, dentists, or chemists in any particular area are not adequate he is empowered to take such steps as he considers necessary to secure an adequate service.

72. The Minister is empowered to arrange with universities and medical and dental schools for the provision of "refresher" courses for doctors and dentists in the service, to contribute towards the cost of these courses and to pay the expenses of doctors and dentists attending them.

LOCAL GOVERNMENT SERVICES

73. This part of the health service comprises the local and domiciliary services which are appropriate to local government, rather than to central government or to any specially devised

machinery. The Bill unifies these services in the existing major local authorities—the county and county borough councils—and provides for the formation of joint boards wherever, exceptionally, this may be found desirable.

74. For most of these services, the Bill requires the local health authorities (as they are to be called) to indicate to the Minister the way in which they intend to carry out their responsibilities and it requires the Minister's general approval. Their proposals so indicated, are to be made known also to the Regional Board and Boards of Governors for the hospital service, to the Executive Councils for the general practitioner services, and to an voluntary organization which to the local authority's knowledge is working in the same field in their area.

75. The purpose of this last requirement is to ensure that the local arrangements are fitted appropriately to the hospital and specialist services for which the Minister is more directly responsible and to the general practitioner services which will be operated within his general regulations and control. The interrelation between the different arms of the health service is reinforced by the provision (already mentioned) for the local health authorities to nominate one-third of the members of the Executive Councils for the general practitioner services and to be consulted by the Minister in the appointment of Regional Boards, Management Committees, and Boards of Governors for the hospital and specialist services.

76. It will also be reinforced in the ordinary process of administration by the personal contacts of the local Medical Officers of Health and the principal medical and other officers of the other bodies, and by various practical devices such as the establishment of local co-ordinating committees of medical and other officers and by the use, wherever feasible, of common employment by different bodies of the same part-time medical or other staff.

77. The various functions comprised in the local government part of the health service are summarized below.

Maternity and Child Welfare and Midwifery

78. The Bill makes it the duty of every local health authority to make arrangements for the care of expectant and nursing mothers and of children under 5 years of age who are attending school and who are therefore not covered by the school health service. Their arrangements will include antenatal clinics for the care of expectant mothers, post-natal and child clinics, the provision of such things as cod-liver oil, fruit juices, and other dietary supplements, and, in particular, priority dental service for expectant and nursing mothers and young children.

79. The Bill transfers these functions from such of the present "minor" authorities—the non-county boroughs and the district councils—as are at present exercising them. But, for co-ordination with the school health services, provision is made for delegating child welfare to "district executives" in the same way—and with the same rights for the minor authorities—as done for the school health service under the Education Act 1944.

80. The same authorities—county and county borough councils—are also made the supervising authorities for the purpose of the existing Midwives Acts; that is to say, they are made responsible for a complete midwifery service for mothers who are confined at home. The midwives are to be employed either by the local health authority itself or by voluntary organizations with whom the authority comes to an appropriate arrangement. Attendance at the confinement is not to be made the general duty of the doctor within the general medical practitioner service, but the midwife will have the usual right—and duty—to call in a suitably qualified doctor in case of need. The general practitioner's services will nevertheless be available to the ordinary extent of general advice and health care to a woman before and after confinement as at any other time.

81. Mothers who for any reason have their confinements in hospital or maternity home will be in the care of the hospital and specialist service. It will also be the object of that service to provide locally for all specialist obstetric or gynaecological care which may be needed in relation to the ordinary domiciliary

service of the local authority. The requirement of Ministerial approval to the local authority's arrangements will link together the two aspects of the maternity service—domiliary and institutional.

Health Visiting and Home Nursing

82. It is made the duty of the local health authority to provide for a full health visitor service for all in their area who are sick, or expectant mothers, or those with the care of young children. This widens the present conception of health visiting (as concerned with mothers and children) into a more general service of advice to households where there is sickness or where help of a preventive character may be needed.

83. It is also made the duty of the local health authority to provide a home nursing service for those who—for good reason—need nursing in their own homes.

84. In both of these activities the local authority can, if it likes and if the Minister approves, make all or part of its provision by arrangement with voluntary organizations to act on its behalf.

Local Mental Health Services

85. The main mental treatment and mental deficiency services are to be part of the new hospital and specialist arrangements under the Bill. Local health authorities, however, are given responsibility for all the ordinary local community care in the mental health service—that is to say, the ascertainment of mental defectives and their supervision when they are living in the community. This part of the service covers also the initial proceedings for placing under care those who require treatment under the Lunacy and Mental Treatment Acts.

Vaccination and Immunization

86. Compulsory vaccination is to be abolished by the Bill, but it is to be the duty of the local health authority to provide free vaccination and diphtheria immunization for anyone who desires them. This service the authority will provide by making arrangements with doctors who are taking part in the general practitioner service—paying appropriate fees to those who undertake it. The vaccines, sera, or other preparations required may be supplied without charge by the Minister to local health authorities and doctors, and the service may, if circumstances demand, be extended to cover vaccination and immunization against other diseases beside smallpox and diphtheria.

Ambulance Service

87. Apart from vehicles which may need to be provided as part of the hospital service, the provision of the main ambulances and hospital transport required for the health service becomes the duty of the local health authorities, either directly or by arrangement with voluntary organizations. In future the local health authority's ambulances may—and must, if necessary—operate outside their own area.

Care and After-care of the Sick

88. Local health authorities are given a new power, and duty where the Minister so requires, to make approved arrangements for the purpose of the prevention of illness and the care and after-care of the sick. This can include such things as the provision of special foods, blankets, extra comforts, and special accommodation for invalids and convalescents and the making of grants to voluntary organizations doing work of this kind (but it expressly does not include cash allowances to individuals or families, which is the function of National Insurance). A charge may be made in appropriate cases.

Domestic Help

89. Under the existing law local authorities are empowered to provide home helps as part of their maternity and child welfare functions, and, during the war, this power has been extended by temporary enactments to enable them to provide domestic help in a wider range of circumstances. The Bill makes this power permanent and extends it to cover the provision of domestic help, subject to the Minister's approval, to any household in which it is needed on grounds of ill-health, maternity,

age, or the welfare of children. The local health authority will be allowed to make appropriate charge for this service.

Health Centres

90. The duty of the local health authorities to provide and maintain general Health Centres, both for their own activities and for the general practitioner services, has already been described.

Health Committees

91. Local health authorities will, in the future, be required to appoint statutory health committees (comparable in many ways to their statutory Education Committees) and to refer to them all matters relating to the discharge of their functions under the Bill. The health committees may be authorized to exercise functions on behalf of their parent authorities, and there is discretion to appoint by co-option expert members who are not members of the authority itself.

GENERAL ADMINISTRATIVE AND FINANCIAL PROVISIONS

Central Health Services Council

92. In paragraph 10 the setting up of new technical advisory machinery by the Minister's side has been mentioned. In more detail, the arrangements are these. To advise him generally on the administration of the health service the Minister is to have beside him a Central Health Services Council. The members are to be doctors, dentists, nurses, and other professional people concerned with different parts of the service, together with people having experience of hospital management, of local government, and of mental health services—all of them appointed by the Minister in their individual capacities, but after consultation with the appropriate representative organizations. The Presidents or Chairmen of six of the principal medical bodies in the country are also to serve on the Council, *ex officio*.

93. The new Central Council will be free to advise the Minister of its own initiative on any expert aspect of the services, as well as on matters expressly referred to it by him. It will report annually to the Minister, who will lay the report before Parliament—with his own comments, if he wishes—unless he is satisfied that it would be contrary to the public interest to publish the report or any part of it.

94. The Minister is empowered also to constitute various Standing Advisory Committees on different technical aspects of the new service. These Committees are not specified in the Bill. They will in fact deal with medical aspects of the service, mental health, dentistry, nursing, pharmacy, and any other matters justifying special advisory machinery. They will deal with questions referred to them either by the Minister or by the Central Council and will have direct access to the Minister as well as to the Council.

Default Powers of Minister

95. The Minister is given default powers against local health authorities and any of the bodies constituted by the Bill—the various hospital bodies, Executive Councils, and others—if they are not carrying out their functions satisfactorily. He can make an order directing them to do whatever may be necessary, and then, if still not satisfied, he may take over their functions, permanently or temporarily, himself.

Position of Officers

96. Regulations made by the Minister may lay down the qualifications and conditions of service of any or all of the officers and employees of all bodies (including voluntary organizations) concerned with providing services under the Bill. In regulating conditions of service or remuneration, it will be his object—as already stated—to use appropriate machinery of discussion and negotiation with representatives of those affected.

97. The Minister is empowered to establish contributory superannuation arrangements for the staffs of hospitals (including the specialist services). Executive Councils, the bacterio-

logical and blood transfusion services, and doctors and dentists in the general practitioner services. The employees of local health authorities will be entitled to the benefits of the existing local government superannuation scheme, which can be modified by regulations under the Bill for staff in the health services in order to secure the maximum of interchangeability with other parts of the general service. The employees of local voluntary organizations can be brought within local superannuation schemes. The general object will be to make arrangements such as will secure freedom of movement between the central and local services, and within these services, and also between services provided under the Bill and other health services.

98. Protection is given to existing officers of voluntary hospitals, Insurance Committees, and local authorities whose functions are transferred or extinguished by the Bill, by providing for their transfer and re-employment by the appropriate authority under the new service or for their compensation if they were previously employed whole-time and suffer loss as a result of the change-over.

Miscellaneous

99. The Bill contains also a number of miscellaneous provisions relating to such matters as the transfer of the property of local authorities and Insurance Committees, the holding of inquiries, the procedure for making regulations and orders, and the repeal or adaptation of the existing law to fit the new conditions.

FINANCE

100. The new service is to be financed mainly from the Exchequer, assisted by a payment of some £32 million transferred from the National Insurance Fund, and partly from local rates with the help of Exchequer grant.

101. The Exchequer will bear the cost of the hospital, specialist, and other centrally organized services, the cost of the family practitioner services, half the cost of the local health authority services, together with the cost of central administration. The rates will bear half of the cost of the local health authority services previously described.

102. The expenditure of local health authorities on their services—including any payments which they make to voluntary organizations for services on their behalf—is to rank for Exchequer grant, calculated in accordance with regulations to be made under the Bill. The grant is to be on a "weighted" 50% basis, with no local health authority receiving more than three-quarters or less than three-eighths of their expenditure.

103. The transfer of the cost of the local authority hospital services from the ratepayers to the taxpayers (together with other changes which are in contemplation outside the scope of this Bill) must profoundly affect the present financial relations between the Exchequer and local authorities. The primary financial effect of the transfer of hospital services from local authorities will be to benefit the richer areas appreciably more generally speaking, than the poorer areas. Radical change will be necessary in the general scheme of Exchequer grants in aid of local authorities, therefore, to secure that over-all the policy of the Government of concentrating those grants so far as possible where the need is greatest is further developed. The whole of this question is at present under consideration by the Government with a view to the introduction of a reformed scheme by the time the new health service comes into actual operation.

104. The financial memorandum attached to the Bill also gives details of the general financial background of the new proposals.

A. THE PRINCIPLES OF THE PROFESSION

The Negotiating Committee, representative of the British Medical Association, the Royal Colleges, the Royal Scottish Medical Corporations, the Society of Medical Officers of Health, the Medical Women's Federation, and the Society of Apothecaries, crystallized the views of the medical profession as a whole on the subject of a National Health Service in the following statement:

"For a quarter of a century the medical profession has stressed the need for a complete health service.

The profession is willing and anxious to co-operate with the Government in evolving this service, for it believes that the knowledge and experience of the profession are indispensable contributions to its success.

It re-emphasizes that good housing, social, economic, and environmental circumstances are the principal factors in the maintenance of health and the prevention of disease. It urges the expansion of medical research.

In the interests both of the public and of medicine, the profession regards the acceptance of the following principles as essential:

I. The medical profession is, in the public interest, opposed to any form of service which leads directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities.

II. The medical profession should remain free to exercise the art and science of medicine according to its traditions, standards, and knowledge, the individual doctor retaining full responsibility for the care of the patient, freedom of judgment, action, speech, and publication, without interference in his professional work.

III. The citizen should be free to choose or change his or her family doctor, to choose, in consultation with his

family doctor, the hospital at which he should be treated and free to decide whether he avails himself of the public service or obtains independently the medical service needed.

IV. Doctors should, like other workers, be free to choose the form, place, and type of work they prefer without governmental or other direction.

V. Every registered medical practitioner should be entitled as a right to participate in the public service.

VI. The hospital service should be planned over national hospital areas centred on universities in order that the centres of education and research may influence the whole service.

VII. There should be adequate representation of the medical profession on all administrative bodies associated with the new service in order that doctors may make their contribution to the efficiency of the service."

Behind these principles are considerations of profound importance to the public and to medicine.

For the medical profession to be converted into a technical branch of central or local government would be disastrous both to medicine and to the public it serves. The doctor's primary loyalty and responsibility should be to the patient.

The interest of the public demands that he should be free—as civil servants and local government officers can be—to act, to speak, and to write on professional matters according to the dictates of his conscience, unhampered by interference from above. He should never be required to be in a position to be required, to modify his standard medical certification at the behest of the State, however concerned the State may be with the solvency of a Social Security Fund.

This independence of professional judgment and responsibility of action, evolved over the centuries, is inconsistent with the conception of the doctor as a civil servant or local government officer, whose first loyalty would be to his employing body. Valuable though these forms of organization and control are in many fields of human activity, they would be fatal to the personal doctor-patient relationship which lies at the heart of good medicine.

The doctor should be the patient's doctor and not the Government's doctor. *The doctor's freedom is the public's freedom.*

A whole-time salaried medical service is inconsistent with free choice of doctor. It would mean the equal distribution of work between equally paid doctors regardless of the wishes and preferences of the public. It would tend to impose a uniformity in a form of work in which initiative and originality are essential. It would tend to bureaucratize what should be a human service.

It would destroy what is a proper incentive with most kinds of people in most kinds of work—the relationship between remuneration and the amount and value of work done or responsibility accepted. It might tend to replace competition for patients by competition to avoid them.

The proposals of the Government must be examined to see whether they lead "directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities." It is not enough to postpone the danger. The public should satisfy itself that the proposals will not tend, sooner or later, to this form of service.

Medicine is an art as well as a science. The family doctor is faced with human problems which for their solution demand not merely science but in addition wisdom, kindness, and knowledge of human nature. He is friend as well as adviser. He can give of his best only where complete confidence exists between patient and doctor. This confidence can exist only under conditions which

leave the patient entirely free to choose or reject a particular doctor. Further, the patient in consultation with his family doctor should be free to choose the hospital, clinic, or other institution at which he should obtain his medical care. He should not be required to choose a particular doctor or to attend a particular institution. There will be those in all sections of the community who will prefer to arrange their medical care for themselves outside the public service. The freedom of the citizen requires not only that he shall be free to obtain his medical care privately but that the arrangement should not be such as to penalize him or his doctor if he does. In practice this means that the citizen should be free to obtain private medical care from general practitioner, consultant, or specialist, that practitioners in the public service shall not be precluded from providing it, and that adequate facilities should be available in hospital for them to do so.

Now that the war is over no compulsion, direct or indirect, should be brought to bear upon any citizen to work in any particular area. This principle should apply to doctors as to others. It would be inconsistent with this principle for doctors to be required by law to obtain permission from a governmental body before practising in any area, whether in the public service or privately, or both. The fact that the Government has decided to collect money from the public for medical services and to enter into arrangements on the public's behalf with doctors to provide them does not entitle a Government to apply direction to doctors merely because they desire to enter into contract with the Government to accept liability to treat the beneficiaries under the Social Security Scheme, in effect the whole population. A satisfactory medical service will be achieved only if it is staffed by doctors satisfied with their terms and conditions of service. A doctor under duress is no more likely to achieve this satisfaction than is any other worker in similar circumstances.

B. THE B.M.A. COUNCIL'S REPORT*

The State recognizes and registers a medical practitioner only when it is satisfied that by education, training, and experience the practitioner is fully qualified to offer his services to the public. Other governmental agencies, central or local, should not apply an additional test. No doctor should be in the position, having passed through the medical curriculum, satisfied the stringent requirements of the General Medical Council—the body established by statute for this purpose—of finding that he is not acceptable to this or that central or local body and so find himself unable to practise his profession, with his prolonged and expensive training and experience wasted. The General Medical Council amply protects the public without the imposition of other statutory conditions by other tribunals.

Doctors have an important contribution to make in the planning, organization, management, and development of health services. Indeed without it a service satisfactory to the public is impossible. They do not seek to control such services, but the public interest demands that at every level of administration there should be adequate representation of the medical profession. Their advice should be

presented by them to administrative bodies by medical members of such bodies speaking with the authority which derives from such membership. This principle applies to central and local bodies alike, including regional bodies and the public health committees of local authorities. This is a matter of public and not only professional interest.

STATEMENT ON THE NATIONAL HEALTH SERVICE BILL

The Council, having considered the Government's proposals, recommends to the Representative Body:

That the following statement of policy on the Government's Bill for a National Health Service be approved:

1. The profession, while anxious and willing to co-operate with the Government in evolving a complete health service, is opposed, on grounds of public interest, to certain important features of the Government's proposals.

ORGANIZATION

2. In the Bill it is proposed that the Minister should assume general responsibility for the service and discharge this responsibility through three main channels. In the case of hospital and specialist services he will delegate the bulk of the administration to new regional and local bodies. He will place the responsibility for domiciliary, clinic, and

* The general principles of this report apply to Scotland as well as to England and Wales with the Secretary of State taking the place of the Minister, large burgh councils taking the place of county borough councils, subject to the modifications which the Bill contains on such points as the provision of health centres by the central instead of the local authority.

health centre services directly on local health authorities (county and county borough councils). He will place the responsibility for general practitioner services on specially appointed local bodies acting within national regulations made by himself.

3. Will this proposed structure secure what the profession has long been seeking—the proper co-ordination and correlation of the country's medical services? Will the individual citizen be well served by the proposed administration? When he seeks attention from his family doctor he will be availing himself of a service administered by the local executive council. If that service is rendered in a health centre he will receive it in premises owned by another local body, the local health authority. If his doctor recommends him for hospital treatment he will pass to yet another administration, that of the regional body.

4. In the case of an expectant mother she may receive her medical care from her family doctor at home or in the consulting room, although the proposals on this point are not clear. She may attend an ante-natal clinic, part of the local health authority's service, receiving it there from a whole-time local authority medical officer. But if she proposes to be confined in hospital she may receive her ante-natal care at a parallel set of ante-natal clinics, this time administered by the regional body and staffed by hospital medical officers. If her confinement takes place at home she may be attended by a midwife appointed by the local authority, a doctor in the family doctor service, and, if specialist help is sought, by a specialist in contract with the regional body.

5. In the case of infectious disease the responsibility for preventing its spread will be that of a local authority, probably a lesser local authority. If a case of infectious disease needing hospital treatment occurs the patient will be conveyed to another service administered at the regional level.

6. There appears to be little immediate prospect of bringing to the general practitioner forms of work which should, in the interests of the patient, be undertaken by him. While the *ultimate* object may be to make unnecessary the provision of medical treatment by the school medical service, what is proposed at the outset and for an indefinite period is that such services shall be separately provided and organized by local education authorities, supervised by the Ministry of Education. No attempt is made to bring together the general practitioner service now rendered to mothers and children in clinics and the main general practitioner service, other than the suggestion that immunization, together with vaccination, should be carried out by general practitioners. To employ general practitioners in clinics is not enough. Much of the work now done in clinics should be undertaken by general practitioners as part of their normal work for those under their care. Child welfare responsibility is to follow educational responsibility, which in many cases will mean that a further authority is involved in health administration, a local authority which is not a county or county borough council.

7. The Association criticizes the proposed administrative arrangements as likely to divide the service into at least three compartments, to perpetuate or create barriers between general practitioner and hospital, between hospital and health centre, between the family doctor service and the local authority clinic services, between local authority medical officers and hospital staffs and general practitioners, as well as between the bodies employing them.

8. The Minister will provide and manage a public health pathological laboratory service for the control of infectious diseases, but local authorities are still to be free to provide

their own laboratory services. No mention is made of the clinical pathological services unless these are to be regarded as part of the specialist service coming under regional administration.

9. At what level can co-ordination best be secured? It is not enough to state, as the Minister stated in reply to questions from the Negotiating Committee, that co-ordination between general practitioner and hospital services can be secured by the policy of administration of the Minister, by the work of the Minister's officers, by the presence of some general practitioner members on regional boards and local management committees; that general practitioners will be responsible for the care of their own patients in general practitioner hospitals, which do not yet exist; that the general practitioner will consult freely with the specialist at the hospital, or work as a clinical assistant, or join his local medical society. There will be only such co-ordination as the administration makes possible.

10. In the Association's considered view, co-ordination should take place at the regional level. Regional boards should assume responsibility for the planning and administration of hospital and non-hospital medical services alike, for the building, ownership, and administration of such health centres as may be developed, for the clinic and other treatment services of local authorities; in short, for all treatment as distinct from environmental services. Responsibility for a completely co-ordinated maternity service, including domiciliary midwifery, for health visiting and home nursing services should rest with the regional body. It is recognized that effective local administration may require that regional boards delegate some of their responsibility to appropriately constituted local or area bodies responsible to them, just as it is proposed to delegate responsibility for individual hospitals to local hospital management committees. The statutory responsibility for the provision of these services should be placed not upon local health authorities but on regional bodies.

11. This proposal raises two problems. There would continue to be a divorce between environmental and treatment services. While this would be disadvantageous, it would be a great improvement on the Minister's present proposals. If the regional principle be accepted there arises the question of what would happen to the local executive council. The Association approves the functions and composition of the local executive council, but to secure co-ordinated administration is of the opinion that it should operate on a regional basis.

12. The Association's view on this part of the Bill may be summarized by stating that effective functional integration can be secured only by concentrating local responsibility, administrative, financial, and other, at one level, and in the Association's view the appropriate level is the one selected for hospital services—the regional level. This regional integration is essential not only to efficient administration but in the interests of the public.

CENTRAL ADVISORY MACHINERY

13. While the establishment of a Central Health Services Council drawing members from all the main health professions with a majority of medical members meets the profession's views, the Association urges the Minister to make certain changes. It wishes particularly to stress the following points:

(a) The Council will give the fullest satisfaction only if its medical members are regarded as fully representative of the medical profession. It is desirable in the public interest to make impossible the appointment of medical

members who are unacceptable to the Minister or to the medical profession. For this reason the Association urges that the medical members should be appointed by the Minister in agreement with the medical profession, a nominee unacceptable to the Minister or the profession being rejected. In addition, there should be a small number of ex-officio members—e.g., the Presidents of the Royal Colleges and the Chairman of Council of the British Medical Association.

(b) The standing advisory committees of the Central Health Services Council, like the standing committees of other bodies, should report through the parent body, reporting to the Minister direct only in circumstances approved by that body, or in an emergency by its Chairman. The Central Health Services Council should itself appoint its committees, standing and other, and determine their terms of reference. Only in this way will the Central Health Services Council become a really effective body.

HOSPITAL AND SPECIALIST SERVICES

14. The Association joins with the Government in desiring a co-ordinated hospital service regionally administered over natural hospital areas, a policy which it has consistently urged in all previous discussions. It is impossible to judge the merits of the proposed hospital administration in the absence of detailed information on the composition of regional hospital boards and local hospital management committees. If such bodies are appropriately constituted, with adequate representation of the medical profession, of experts in the voluntary hospital field and, in the case of the regional boards, of the universities, the proposals may, from the administrative point of view, conform to the profession's repeatedly expressed desires. If, on the other hand, the representatives of local health authorities are to be placed in a majority on regional hospital boards or local hospital management committees, the proposals will be in direct conflict with the views of the profession. The Government is urged to embody proposals for the composition of these bodies, and of the boards of governors of teaching hospitals, in the Bill, and not to leave them to be dealt with subsequently by regulation.

15. The method of the group management committee, common in local authority organization, does not do away with the need for an individual committee of management. Accordingly, the Association urges the establishment for each hospital of a committee of management, to be responsible for its day-to-day administration in conformity with the plan of the regional hospital board, and a medical staff committee in close relation to, and represented upon, the committee of management.

16. On the subject of ownership, the Association recognizes that the Government's proposals raise serious issues which will be the concern of the public as a whole. The adoption of these proposals as they stand will inevitably involve a loss of local personal interest, and the discouragement of local support, whether in the form of contributions or of service. At present the local hospital, whether voluntary or council, commands a great deal of local pride, resource, and initiative, amounting sometimes to individual sacrifice for the community's good. Somehow or other these things must be preserved. These arguments for the preservation of the individual character and the local relationships of hospitals are not mere sentimentality. They bear closely, for example, on the hospital's capacity for innovation and experiment, its power to attract nursing and other staff and the confidence of the local people in their local hospital.

The Association has consistently pressed for an effective and appropriately constituted regional body with sufficient powers, financial and other, to secure the planned development of hospital services. In the Association's view the Minister should accept responsibility for all hospital provision and maintenance, voluntary and council, being advised on the allocation of the necessary centrally provided moneys by regional bodies. Such an arrangement would secure to the Minister and to the regional body all necessary power in the organization and development of the hospital service of its area, and it is unnecessary and undesirable for the Minister to proceed to assume actual ownership of hospitals, council or voluntary.

17. The Government's proposals might threaten private consulting practice despite the fact that the proposal of part-time service for some consultants is based on the assumption that private practice will be facilitated. The State, as owner of the hospitals, will control the private or semi-private accommodation and so will be free to convert private accommodation to semi-private accommodation and either to public accommodation when it so desires. In this way, and by its control of fees charged in private accommodation, it will control private consulting practice in so far as it is conducted in hospital premises. There will be scope for people to obtain additional amenities—e.g., private rooms where these are not medically necessary—by payment of the extra cost involved. But it appears that private accommodation will be restricted to particular hospitals where provision can be made "in separate parts of the hospital," and that the facilities will be limited to specialists taking part in the new service. This provision should not exclude the recognition of rooms and beds in the main hospital buildings as private accommodation. The Association is opposed to a restriction of the use of private accommodation of a particular hospital to specialists taking part in the new service.

In the public interest the conditions imposed should not be such as would lead or compel consultants or their patients to use nursing home or similar accommodation dissociated from the hospitals for private consultation and treatment.

Teaching Hospitals

18. The proposals for the administration of teaching hospitals can be judged only when fuller information as to the composition of the proposed boards of governors is known. It is not clear to what extent hospitals affording postgraduate clinical teaching and research will be regarded as teaching hospitals for the purpose of these arrangements. It is not clear what part the University Grants Committee will play in financing teaching hospitals. Only when fuller information is available can the proposals in relation to teaching hospitals be judged.

LOCAL CLINIC, DOMICILIARY, AND WELFARE SERVICES

19. The proposals under this heading have been the subject of comment in earlier paragraphs. The Association dislikes the proposals to place a statutory duty on local health authorities in respect of school medical and maternity and child welfare services, domiciliary midwifery, health visiting and home nursing services, vaccination and immunization, and a general ambulance service. Similarly, the Association is opposed to the proposal to place the responsibility for the provision and maintenance of health centres, dental centres, and similar premises upon the local health authority. The health centre no less than

the hospital should be the responsibility of the regional board. In the case of the ambulance service the case for regional organization is no less strong, for this, the committee believes, is the only way of bringing to an end the irritating limitations imposed by local authorities on the use of their ambulances outside their areas. These services should, in the Association's view, be administered, together with the hospital service, at the regional level.

FAMILY PRACTITIONER SERVICES

20. An objective from the outset will be the development of the health centre system. The profession is deeply interested in health centres—indeed, the general idea was first put forward by the profession itself. But it would be contrary to the public interest to proceed to a rigid health centre policy without widespread experiment into the merits and demerits of different types of health centre in different types of area. The Association suggests an immediate experimental investigation, under medical guidance, of health centres of varied types and functions. Some advantages, such as the organization of nursing and clerical facilities, the provision of premises specially built for the purpose, are obvious. Some disadvantages, particularly from the point of view of the public, are no less obvious. For example, patients will travel greater distances, they will suffer some loss of privacy, there may well be a loss of the personal touch. No details are given of the kind of health centre it is proposed to develop. The health centre outlined in the Coalition White Paper can be fairly described as an aggregation of doctors' consulting and waiting rooms, with common nursing and clerical help. This does not meet the real need. What general practitioners need, above all, is the provision of facilities for fuller diagnosis, with special emphasis on pathology and radiology. The extent to which such facilities can be made available in health centres should be a matter of widespread experimentation before the lines of central policy are laid down.

21. The building of health centres will take a considerable time. Pending their construction the effect of the Government's proposals will be not what it seeks, the encouragement of group medicine, but the opposite. The abolition of goodwill will of itself destroy the present basis of partnership agreements, breaking up partnerships into bits of individual practitioners who may or may not make such arrangements between themselves. This may be still the case when health centres are in action. Further, no indication is given that the Government contemplates, in its proposed arrangements, the status of "assistant." It appears that all general practitioners in the proposed service, whatever their age or experience, will practise as individuals.

22. If the duty to provide and maintain health centres is vested in local health authorities, it will be difficult to avoid the present limitations of local facilities to the residents of particular local government areas. It is doubtful whether a health centre provided and maintained by one local authority would be available to the residents in an adjacent local authority area. This would involve some restriction of the patient's free choice of doctor. As has been urged in an earlier paragraph, the ownership and administration of health centres should be vested in the regional body.

23. The following statement was made by the Minister of Health in the House of Commons on Thursday, December 6, 1945:

"1. The Government have not yet finally decided upon the proposals which they will be submitting to Parliament for a National Health Service.

2. They believe, however, that it will be incompatible with the provision of an efficient service that the future exchange of medical practices and the creation of new practices within that service should be left entirely unregulated, and that no effective steps should be taken to secure a proper distribution of doctors to fit the public need.

3. I appreciate that intervention in this field, in whatever form it may take, will probably have the effect of preventing the sale and purchase of the practices of doctors taking part in the new service, and the Government therefore think it right to give warning of this probability at once and in advance of the formulation of their full proposals.

4. At the same time and in order to allay the natural anxieties of doctors already in practice, or coming into practice from the Forces or elsewhere, the Government wish to make it clear that there will be an appropriate measure of compensation to doctors in respect of loss of capital values directly caused by the new arrangement.

It is intended that discussions should be undertaken immediately with the profession's representatives with regard to the steps to be taken to give effect to this decision."

24. The Government proposes to control the distribution of doctors and recognizes that such control will destroy the selling value of practices wholly or partly in the public service. The method of control will be to require entrants to the public service to apply to the local executive council, which will pass the application on to the Central Committee on the Distribution of Medical Practices, for decision as to whether the applicant is to be allowed to practise in a particular area being made by the latter body.

A central point of Government policy is the decision to achieve a better distribution of general practitioners under control. In the view of the profession such control is unnecessary and undesirable. An examination of the figures of the distribution of doctors in relation to population before the war shows, admittedly, an irregularity of distribution and some under-doctored areas. Generally speaking, these areas are not local government areas; usually they are pockets and not complete towns or counties. But it must not be thought that such irregularity merely exhibits a preference on the part of doctors for wealthier areas. For example, the ratio of general practitioners to population shows that Barrow-in-Furness, Darlington, and Macclesfield were in the years before the war provided with more doctors per thousand of population than Richmond, Rugby, or Winchester. When the age and health record of the local doctors has been examined, as it has been by the Central Medical War Committee during the war, it has been commonly shown that apparently over-doctored areas are, in fact, no better served in terms of medical man-power than apparently less well-doctored areas.

25. The introduction of National Health Insurance was briskly followed by a more even distribution of doctors. The introduction of a scheme available to the whole community will of itself exercise a very considerable influence in evening out medical distribution. The main problem which, in the Association's view, will remain unsolved by the introduction of a 100% service is the problem of the sparsely populated rural area. The method of extra inducement can and should be applied to solve the

problem of the sparsely populated area, as it can be applied—if experience shows it to be necessary—to other areas. In addition, the Minister could retain the powers given in Section 15 of the National Health Insurance Act, 1911 (and in Section 37 of the Act of 1936), enabling appropriate arrangements to be made in areas where medical service is inadequate. The profession will willingly establish an advisory machinery for helping to assist incomers to practice to select areas where the need is greatest. What it is opposed to as both unnecessary and undesirable is the form of negative direction proposed by the Government.

26. It was the Government's proposals for control which, because of their anticipated effect on the capital value of practices, led it to put forward proposals for compensation. Clearly there should be full compensation for any adverse effect on capital values occasioned by the Government's proposals. But, in the Association's view, the Government should not proceed with proposals to control the distribution of doctors if improved distribution can be secured without such control. If the "control" proposals are not proceeded with, it will be unnecessary to interfere with existing arrangements for the buying and selling of practices. The profession can and will make possible by its organization the entry or re-entry of demobilized practitioners to general practice under terms which are not onerous.

Clearly the proposal to abolish the buying and selling of practices is a crucial issue. Already the profession has expressed the view "that it is in the national interest and essential to the independence of the profession that doctors should continue to own the goodwill of their practices." The three proposals (a) to abolish buying and selling, (b) to institute basic salaries, (c) to control the distribution of doctors, considered either separately or as related parts of the plan, would take the profession much nearer the whole-time State-salaried service to which it is so strongly opposed.

27. It is understood that a substantial proportion of general practitioner remuneration will be derived from basic salary. The Association can find no justification for this proposal. It desires that the main, if not the only, element in general practitioner remuneration should be the choice of the individual doctor by the individual patient. The basic salary proposal, particularly if the proportion of the total remuneration is substantial, will lead to whole-time salaried service—something to which the profession is wholly opposed. It believes that in the future, as at present, there will need to be an appropriate proportion of assistants to principals in general practice, those assistants being employed by principals. It would be appropriate to establish agreed general salaries for assistants. It would be reasonable to require that a practitioner shall not become a principal in the new service until he had served for a prescribed period of time as an assistant. When he becomes a principal his remuneration should be related to the number of patients on his list.

28. If the Government proposes to pay basic salary only when a certain minimum number of patients have chosen the doctor, its proposal is superfluous. If it proposes to pay a basic salary to a practitioner entering the public service, however small the number of patients who are on his list, then the proposal is extravagant.

AMOUNT OF COMPENSATION

29. After discussion between the Ministry of Health and the Compensation Subcommittee of the Negotiating Committee the following letter was sent to the Minister:

March 8, 1946.

DEAR MR. BEVAN,

The Compensation Subcommittee of the Negotiating Committee has entered into discussions with the Ministry on the question of compensation, without accepting the policy from which the necessity for compensation arises. The medical profession is in no way committed to the policy of abolishing the custom of buying and selling goodwill. Indeed it has in the past expressed its opposition to this policy.

Important principles affecting the freedom of the medical profession are involved, and the amount of money offered by the Government in compensation is irrelevant. The Government's proposals must be considered as a whole and not merely in terms of finance.

The view of the Subcommittee is that if the Government persist in this policy, and Parliament approves, then the sum of £66,000,000 which the Government, after negotiations with the Subcommittee, now offers may, on the evidence available, be taken to represent the aggregate capital loss involved in respect of the goodwill of general practices.

The Compensation Subcommittee understands that this sum of £66,000,000—

(a) is based on the Government's estimate that 17,900 principals will enter the National Health Service;

(b) will not be subject to increase if in fact more than 17,900 principals so enter;

(c) will be subject to reduction if the number of principals so entering is below 17,700; the reduction for each principal in defect of 17,700 to be 1/17,900 of £66,000,000

Yours sincerely,

(Signed) CHARLES HILL,

Secretary.

The Right Hon. Aneurin Bevan, M.P.

SOME OTHER POINTS

Civil Rights of Doctors

30. It should be secured in the Bill that doctors who participate in the National Health Service are not disqualified to serve as Members of Parliament, as members of local authorities and of any bodies concerned with the administration of the service, including regional boards, local hospital management committees, and local executive councils.

Industrial Medical Service

31. The exclusion from the scheme of the industrial medical service cannot be justified. The medical supervision of the worker at the factory should be linked with the supervision of his home environment as part of the same health service. Medical services in industry are of comparatively recent growth, and the opportunity should not be lost of integrating them with the main health service.

Specialists in the Public Health Service

32. While it is proposed to inaugurate selection committees for the appointment of specialists there is nothing in the Government's proposals to indicate that senior specialist officers in the Public Health service will be appointed otherwise than by local authorities.

Medical Research

33. No new proposals are advanced for the expansion and development of medical research. The facilities and resources for medical research should be greatly increased.

THE PROPOSALS AND THE PRINCIPLES

34. There are four of the profession's essential principles upon which the Government's proposals have a particular bearing:

PRINCIPLE I

The medical profession is, in the public interest, opposed to any form of service which leads directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities.

35. The State will own all the hospitals in which consultants work, will appoint the governing bodies of hospitals, and, through regional boards, will employ the consultant to work in or from its premises, the consultant being employed on a whole-time or part-time basis. Whether the hospital proposals will lead directly or indirectly to consultants and specialists becoming "full-time salaried servants of the State or local authorities" will largely depend on the composition and functions of the regional board, the local hospital management committee, the board of governors of the teaching hospital, and the committee of management of the individual hospital.

36. General practitioners will be in contact with local authorities, half professional and half lay. At the earliest possible moment they will conduct their public general practices in premises owned and administered by a local authority. They will be remunerated in substantial part by salary. New entrants to public general practice will be appointed by a mainly medical body set up by the Government and working under its general direction. The Government's proposals, in the Council's view, will lead to general practitioners "becoming full-time salaried servants of the State or local authorities."

PRINCIPLE IV

Doctors should, like other workers, be free to choose the form, place, and type of work they prefer without governmental or other direction.

37. For the reasons set out in earlier paragraphs the Government's proposals are in conflict with this principle.

PRINCIPLE V

Every registered medical practitioner should be entitled as a right to participate in the public service.

38. The Government's proposals violate this principle. They contain no provision whereby a medical practitioner could claim the right to take part in the service somewhere. The local executive councils will consider not only the need for a new practice or replacement, but also the suitability of the applicant. The applicant, although recognized and approved by the General Medical Council, might therefore find himself or herself excluded from the service, either in particular areas or in every area.

The present proposals, in the Association's view, should be replaced by provisions similar to Sections 35 (2) (b) and 36 of the National Health Insurance Act, 1936. Section 35 (2) (b) secures a right on the part of any medical practitioner who so desires of being included in the lists of medical practitioners who have agreed to attend and treat insured persons. Section 36 is as follows:

"If the Minister, after such inquiry as may be prescribed, is satisfied that the continued inclusion in the list of any medical practitioner would be prejudicial to the efficiency of the medical service of the insured, the Minister may remove his name from the list."

PRINCIPLE VII

There should be adequate representation of the medical profession on all administrative bodies associated with the new service in order that doctors may make their contribution to the efficiency of the service.

39. The profession is promised medical representation on central advisory bodies, on regional boards, and on local hospital management committees. Although it is promised a majority on the Central Health Services Council, the composition of regional boards and local hospital management committees, as of boards of governors of teaching hospitals, is not known. Even though local health authorities are to be required to establish public health committees, there is not to be a requirement to co-opt doctors and other non-members of the authority with experience of the health services. Thus the Government's present proposals present some points of conflict with this principle.

PLAN FOR A HOSPITAL SERVICE

A few days before the appearance of the National Health Service Bill the British Hospitals Association published its plan for a national hospital service within a National Health Service. Briefly it proposes that voluntary hospitals should be retained alongside local authority (or State) hospitals, but working together in a service properly planned and organized over regions and centrally directed on a national basis. The Minister of Health would assume general responsibility for the direction and financing of the hospital service and would appoint, after consultation with the appropriate bodies, a central hospitals board, to which, subject to his veto, he would delegate major duties and responsibilities, including framing national policy. This board would be wholly or largely representative of doctors, voluntary hospitals, local authorities, dentists, nurses, and pharmacists. Regional hospital services would be planned by regional hospital boards, also appointed by the Minister, and each region would be associated with one of the medical teaching centres. The regional board would decide what services were required from each hospital in its area and have the necessary executive powers to ensure that its plans were carried out. These regional boards would be wholly or mainly representative of the interests concerned, including the universities. The individual hospital, through its committee of management, would be entirely responsible for the internal management and general conduct of its affairs. Voluntary hospitals would retain in trust their buildings and assets, but would receive payment from the State for services required and rendered. They would still be free to attract personal interest in their work and support for special purposes, for activities which are outside the scope of the national service, and for the general improvement of services, including the comfort both of patients and of staff.

In an introduction the British Hospitals Association states that the plan provides on a secure financial basis a comprehensive service free to the citizen, combining State resources with all that is best in existing services, including the voluntary hospitals. It maintains a balance between the organization required for a national service on the one hand and the obvious dangers in any national plan—loss of the personal and human touch and loss of local interest—on the other. The success of the voluntary hospitals has been chiefly due to their methods of direct management and to the widespread personal interest which they have attracted to their work.

APPLICATION OF NUTRITION TO PUBLIC HEALTH*

SOME LESSONS OF THE WAR

BY

H. E. MAGEE, D.Sc., M.B.

The war of 1914-18, and the food problems which then arose, more than any other event in the past 50 years focused attention on the importance of food for health. The stream of new knowledge of nutrition coming in increasing volume from research centres in different parts of the world after 1918 soon began to affect medicine in all its branches, especially public health. By the early 'twenties the discoveries in the physiology of calcium and phosphorus and of vitamin D were having effect on the prevention and treatment of rickets; by the end of the twenties the feeding tests of Corry Mann and of Orr and his colleagues¹ had demonstrated the high nutritive value of milk, and, by inference, many defects in the diets of large numbers of people. Those in charge of the public health were quick to apply these discoveries, and issues of preparations of calcium, vitamin D, and dried milk to mothers and children became a common practice in all welfare centres. The general body of the profession were not behind their colleagues in the public health services.

It had to be admitted, however, that the new knowledge of nutrition lacked wholeness, and required integration and synthesis of its various bits and pieces before it could be expected to impress those in control of the health of nations. It was appropriate, then, that this task should be taken up by the Health Organization of the League of Nations: first, because nutrition is of universal significance; and, secondly, because it is a health matter not to be dominated by other interests—agricultural, economic, or what not.

League of Nations Commission.—The Technical Commission of the Health Organization was the first international body of authoritative standing to make a comprehensive statement on the principles of nutrition. The Commission was succeeded by the Mixed Committee, which, in a series of reports, indicated the effects of the application of the new knowledge on the agriculture, economics, industry, and commerce of nations. It recommended the participating countries to set up national committees on nutrition, which would seek to put into effect the Commission's recommendations. In Great Britain a small expert committee of physiologists had been established by the Ministry of Health in 1931. It was succeeded in 1935 by a committee appointed by the Minister of Health and the Secretary of State for Scotland, representative of physiology, clinical and preventive medicine, agriculture, social and economic affairs, and statistics. The committee welcomed the report of the Technical Commission, expressed general agreement with it, and said that "the Commission has set up a new and high level of nutrition which we have adopted." This is noteworthy in view of the many statements made during the war that the standards of the Technical Commission were intended to be minimum.

Advisory Committee.—The Advisory Committee, through the machinery of the Agricultural Departments and the Board of Trade, accumulated statistics of home production and of imports and exports of food, and studies of the food consumption of families of different occupations in town and country were initiated or conducted by the Health Departments. The Ministry of Labour at the request of the Committee carried out a budgetary survey of several thousand families throughout the country. Much of the knowledge gained in these studies was published in summary form.² The budgetary survey made by the Ministry of Labour was published independently.³

War.—These studies were pursued as a purely peacetime activity without reference to war. When war broke out the information accumulated was of great assistance to those concerned with drawing up a food policy for war. Without this information the supply and distribution of food could not so readily have been placed on a scientific basis. The wartime

food policy was, in fact, the first real try-out of the science of nutrition.

The Food Policy

Mode of Application of Nutrition.—In applying the science of nutrition the following five points had to receive attention. These are stated briefly and are illustrated by examples which indicate roughly how the wartime food policy was put into effect.

1. *Production of Vegetable Foods.*—Account had to be taken of differences in yield of nutritive value per acre for different crops. Potatoes and certain vegetables come high in order of yield, one acre of potatoes yielding, on the average, nearly 50% more calories than one acre of wheat, and one acre of cabbage yielding about as many calories as one acre of wheat. It was therefore very desirable to produce the maximum of potatoes and vegetables. People cannot, however, live on potatoes and vegetables alone, even in wartime, and the demands of farming practice had to be taken into account. In addition, potatoes and vegetables are our chief native sources of vitamin C, and it was likely that imports of fruit, which was an important source of vitamin C before the war, would have to be restricted.⁴

2. *Production of Animal Food.*—First place had to be given to milk, well called the keystone of the nutritional arch. It was important to prevent production falling as in the last war, and even to increase it if possible. First priority in animal-feeding stuffs was therefore given to dairy cattle, and throughout the war production was fairly well maintained. Taking production in 1936-7 as 100, it was 101 in 1938-9 and 96 in 1944-5. Consumption, however, went up and up during the war, made possible by diverting more and more milk from manufacture to liquid consumption. Another important advantage in giving milk production priority over all other animal foods is that it provides a better return in human food than production of meat or of any other food of animal origin.⁵ The dairy cow, for instance, converts about 60% of the energy content of its food into energy in the form of milk and meat. The corresponding figure for the beef animal is about 10%; the figures for pigs and poultry are intermediate. Pigs and poultry, which feed mainly on cereal grains, are competitors with man for these foods; their numbers had therefore to be drastically reduced.

3. *Imports of Food.*—Important modifications in shipping were introduced to achieve the maximum importation of nutritive material in the limited shipping space available for food. Carcasses of meat were telescoped, and later the bones were removed so that more could be packed into a given space; in the later years of the war some dried meat was imported. Shell eggs occupy much space in relation to nutritive value; by having them dried we were able to increase by many times the amount of nutrients in the form of eggs per unit of shipping space. For about the first year of the war imports of fruit were restricted to the orange, because, all things considered, the orange beat all competitors. Later, when the shipping position deteriorated still further, all imports of fruit had to cease.

4. *Integration of Food Supplies.*—In order to provide a balanced diet for the average person the schedules of production and of imports of all foods were integrated and collated with the varying needs of different sections of the population. Schedules of production and of imports were so arranged as to approximate as closely as possible the requirements of the population computed from nutritional standards. The relative steadiness of the rations of different foods throughout the war is eloquent testimony of the completeness with which the schedules of production and imports were fulfilled.

5. *Distribution of Food.*—In planning for distribution according to physiological requirements, the first step was to define the needs of special sections of the population and then to earmark allowances of appropriate foods to meet them. Those who had thus to be taken into account were expectant and nursing mothers, children, adolescents, heavy workers, and invalids. Having made provision for these categories, a fair division of the remaining foods amongst the whole population would, it was believed, meet the essential requirements of everyone. A cardinal principle was that rationing of bread and potatoes should be avoided if at all possible. Bread is the most important elastic reserve to cover variations in energy requirements, and so long as bread and potatoes remained unrationed there could be no real hunger. However much people may have complained about their food, one fact stands out above all others—no one

* The Milroy Lectures (abridged), delivered before the Royal College of Physicians in 1945.

The specific needs of mothers and children are constructive and protective nutrients. These were provided by the National Milk and Vitamin Schemes and by special priorities for eggs. School-children had the Milk-in-Schools Scheme, school meals, and half a pint (284 ml.) of milk daily delivered at home. Adolescents also had half a pint of milk at home, and they could obtain the national milk cocoa at their place of work. Many efforts were made to provide more for adolescents, but always the administrative problems involved were too complex. Heavy workers were able to obtain the extra food they required from their canteens; those who had not access to such canteens could obtain extra food at the British Restaurants. Agricultural labourers, miners, and certain other classes of heavy workers who could not obtain extra food from community feeding centres were given an extra ration of cheese. The special requirements of invalids were looked after by a committee of the M.R.C. Hospitals had special allowances of certain foods—e.g., milk, dried milk and eggs, and fish. Religious customs and the habits of vegetarians received due recognition. Finally, the ingenious "points" scheme made it possible for people to vary their diets somewhat according to taste.

Responsibility for Food Policy.—The planning, administration, and implementation of the wartime food policy was, of course, the responsibility of the Ministry of Food. The several other Government Departments concerned in one way or another with food were always consulted whenever major decisions were taken. The Ministry of Food naturally maintained particularly close contact with the Departments of Health and of Agriculture. The Ministry of Health, as the Department responsible for nutritional policy, had the special task of advising the Ministry of Food on the health aspects of food policy. The Ministry in discharging this task endeavoured to see that the nation was provided with a diet which would maintain health, stamina, and morale at a sufficiently high level to stand the strain of total war. The thesis I put forward is that this aim was in large measure achieved.

Departures from Desirable Levels of Consumption.—While the food policy in the main conformed to scientific principles, there were certain deviations from them, notably in regard to milk and bread.

Notwithstanding the National Milk Scheme and the other priority schemes for supplies of milk, consumption during the years of war was below what was considered desirable from the health point of view. The Advisory Committee reckoned that if everybody in Britain were to receive the desirable quantity of milk the overall average consumption would be about 0.88 pint (500 ml.) per head daily. The consumption in 1936-9 averaged 0.41 pint (233 ml.), in 1940-1 0.56 pint (318 ml.), and in 1944-5 0.66 pint (375 ml.).⁴ Consumption was therefore three-quarters of requirements at the end of the war.

The bulk of the bread consumed till April, 1942, was made of white flour of about 68-75% extraction, which is almost devoid of protective nutrients. Bread of this sort has never met with the approval of experts in nutrition, but the activities of the enemy rather than scientific advice prevailed with the Ministry of Food. It was the dearth of ships rather than the arguments of the scientists which persuaded the Ministry of Food to raise the milling extraction rate to 85% in April, 1942. Many experiments by workers of the M.R.C. and of the Cereals Research Station, Ministry of Food, showed that this rate of extraction gave the maximum nutritive value of wheat with the minimum of indigestible residue. The lowering of the extraction rate to 80% in January, 1945, reduced appreciably the nutritive value of bread.

Effects of Food Policy on Food Consumption.—The Combined Food Board published global figures for foods moving into consumption up to 1943-4 and compared them with corresponding figures for 1934-8.⁵ Important increases were: for potatoes, 45%; vegetables, 34%; milk and milk products, 28%; and grain products, 17%. Important decreases were in tomatoes and citrus fruits, 50%; other fruits, 44%; poultry and fish, 39%; sugar, 31%; meat, 21%; and fats, 16%. Eggs were down by only 6%, which may seem strange; the explanation is that the eggs were imported without shells and most of the water.

Nutrients Available for Consumption.—The amounts of nutrients available for consumption give a truer picture of the nutritional value of the national diet. It is important to note that the amounts published by the Combined Food Board⁶ are

those available for consumption and not necessarily the amounts consumed. Wastage of food was greater before than during the war, and there can be little doubt that many people consumed more food during the war than before it. There are no figures available, but figures would be an unnecessary refinement. The additional muscular exercise spent by large sections of the population in longer hours of work, more intensive effort, and other extra activities such as A.R.P., Home Guard, and allotment work required extra energy, which had to come from the food if wasting was to be avoided. There was no substantial or progressive decline in the weight of adults of either sex during the war, as the special body-weight survey of the Ministry of Food has shown. This survey was carried out on the same individuals—several thousands—at regular intervals from 1943. Therefore the increased output of energy must have been in the main balanced by increased consumption.

Since the estimates in the table are an overstatement of consumption, particularly for the pre-war years when wastage was greater, it follows that the actual increases in consumption during the war years are greater than the figures of the Combined Food Board would indicate, while the real decreases are smaller.

Calories show an apparent decrease of 130 per head daily, but, for the reasons just given, it is probably not real. Total protein was up by nearly 5 g., due mainly to increases of 4 g. in milk protein and 6 g. in cereal protein, but animal protein fell by nearly 3 g. Fats were down by 16 g., but calcium was up by 360 mg. because of increased consumption of milk and vegetable and the fortification of flour with chalk. The amounts of vitamins B₁ and C available for consumption were also increased—B₁ by 0.71 mg. and C by 15 mg. per head daily. The increase in B₁ did not become apparent until 1942, when 85% extraction flour became compulsory. The worst year of all for food was 1941, and yet the figures show that the actual diet was little different from the pre-war one. Fat consumption was down by 18 g., vitamin C by 10 mg. protein was up by 2 g., calcium by 10 mg., and there was little change in the other nutrients.

Inequalities in Distribution.—The national diet as a whole was unquestionably better balanced during the war than before it, but it was important to know how it was distributed. For this purpose the Ministry of Food in late 1940 began to conduct systematic surveys of family diets on a large scale. The Ministry of Health gave much advisory and technical assistance in the conduct of these surveys. The results are still confidential, but it can be said that the distribution of different foods and the consumption of different nutrients are much more equal and more in accordance with requirements as between families of different income levels than before the war. This, of course, was achieved by rationing and priorities, by good wages, and by subsidies on staple foods.

The report of the survey of family diets made in the West Riding of Yorkshire in 1935-7 by Potts and myself⁷ shows that consumption of many important nutrients was well below the desirable level—namely protein, calcium, and iron, and, there can be little doubt, in the important vitamins. Knowledge of the vitamin content of foods at that time was insufficient for a satisfactory calculation of vitamin consumption.

I am at liberty to quote some recent findings of the Ministry of Food's dietary survey. Compared with the intake of nutrients by the West Riding families in 1935-7, the diets of working-class families in 1944 were much superior. For instance, for all the Yorkshire working-class families the average consumption as a percentage of requirements was: calories, 99%; protein, 88%; iron, 94%; calcium, 41%; compared with 105%, 117%, 134%, and 79%, respectively, for the families of manual workers, of similar composition to the Yorkshire families, in the third quarter of 1944.

Decreases in Consumption.—The nutritive value of the wartime diet was also improved by the fall in the consumption of sugar, which was 31% less in 1943-4 than in 1934-8. An important consequence was that less carbohydrate was consumed which lacked corresponding amounts of the B vitamins for complete physiological oxidation. The B vitamins necessary for the oxidation of sugar must be drawn from other foods. The greater the quantity of sugar consumed the more is the balance of the diet likely to be upset.

Effects of Dietary Changes on Health

Towards the end of 1941 steps were taken by the Ministry of Health to obtain systematic and up-to-date information about the nutritional state of the population. The Chief Medical Officer arranged with the Rockefeller Foundation for Dr. Sydenstricker, of the University of Georgia, to spend a year in Great Britain making clinical surveys of the nutritional state. After Sydenstricker's departure his surveys were continued by other clinicians experienced in deficiency diseases. Systematic studies of the heights and weights of school-children were also made, and further information showing the effects of the war-time diet on health was obtained from surveys carried out by M.R.C. workers, local health departments, and others. Thus during most of the war the Government had under constant surveillance the total amounts of food available, the way in which it was distributed between families, the nutritional status of the population, the growth rate of children, and other information indicating how the public health was reacting to the changes in diet and the strain of war. One of the most conspicuous and surprising phenomena of the war was the way the health, vigour, and stamina of the population were maintained in spite of all the stresses, physical and mental, to which they had been subjected. Not everyone, it is true, was subjected in the same degree to the stresses of war, but no one could escape the general anxiety, the trials of the black-out, the harder work, and the lack of amusements. In addition, housing and the general environmental conditions were worse than they had been for years, and there were fewer doctors, dentists, nurses, and health visitors to attend to the needs of the people. Nevertheless, the general state of the public health during the war was in many respects better than before it.

Growth of School-children.—My colleague Dr. Bransby, with the co-operation of the Ministry of Education and school medical officers, has been, since 1940, making systematic studies of growth in children in several parts of the country. In evacuation areas, like Liverpool and London, as well as in neutral and reception areas, heights and weights were higher in 1943 than those of children of the same ages in the same areas before the war. During 1940–1 there were in many areas small regressions compared with pre-war, but these generally had been more than made good by 1943. In a special study of about 18,000 children living at home, mainly in the evacuation areas but including a few neutral areas, the mean height was 1/4 in. (0.64 cm.) and the mean weight about 6 oz. (170 g.) greater in 1943 than in 1940. Bransby's¹ most recent findings are in Table I. They show consistent increases in the rate of

TABLE I.—Average Percentage Increases in Growth Rate in 1944 over 1938 and 1939 for School-children in 21 Areas of Great Britain

Age (years)	4	6	8	10	12	14
Height { Boys	0.4	0.1	0.8	1.1	0.7	0.6
Girls	0.3	1.1	0.6	1.5	0.4	0.1
Weight { Boys	1.7	1.7	3.1	4.1	3.1	2.5
Girls	2.9	1.8	3.8	6.7	2.1	2.9

growth of 0.1 to 1.5% in height and of 1.7 to 6.7% in weight in 1944 over the growth rates of children of the same ages in the same areas in 1938 and 1939. The improvement in growth rate was not confined to school-children, for Milligan and Lewis-Faning² found that infants in Glossop in the first year of life grew more rapidly in 1940–2 than before the war.

Health of Mother and Child.—The results of important investigations carried out in recent years have done much to remove any doubts there may have been that consumption of adequate diets by the mother plays an important part in reducing the incidence of the ills and accidents peculiar to childbirth. The best evidence is of comparatively recent date, but many previous attempts had been made to throw light on the matter. Mellanby³ in 1929 found that the puerperal morbidity of about 140 women receiving daily supplements of vitamins A and D during the last month of pregnancy was only one-quarter that of an equal number of women who received no supplement. Theobald⁴ carried out a similar test on a group of 50 pregnant women; they were given, from the fifth month, daily supplements of calcium lactate and vitamins A and D. The incidence of symptoms of toxæmia—albuminuria, oedema, headaches, etc.—was less than half that in a control group of women. These and other similar tests⁵ supported the conviction in the

minds of many workers on this subject that improvements in the diets of pregnant women would go a long way towards reducing the morbidity and mortality of mother and child.

Toronto Test.—A comprehensive experiment was obviously desirable; such a one was carried out by Ebbs, Tisdall, and Scott.¹¹ They ascertained the diets of about 400 women in the fourth month of pregnancy in Toronto. The diets of 170 were found to be fairly good, and they were further improved by vigorous propaganda. The diets of the remainder were deficient in practically all the known nutrients; but for 90 of these women the defects were remedied by daily supplements of appropriate foods. The poor diet of the other 120 remained unchanged. Thus, for the last 4½ months of pregnancy, 260 women were receiving a well-balanced diet and 120 a diet deficient in most nutrients. The women and their babies were observed until 6 months after labour. During pregnancy the mothers getting good diets had better health, fewer complications—toxaemia, haemorrhage, miscarriages, premature births, stillbirths, and mastitis—and were, in general, considered to be better obstetrical risks than the women on the poor diets. The incidence of illness in the babies and the number of deaths during the first 6 months of life were much lower in the well-fed groups. For instance, 21% of the babies in the badly fed group had frequent colds and 5.5% had pneumonia, compared with 4.7% and about 1%, respectively, in the well-fed groups. The incidence of anaemia was also much higher in the deficiently fed groups.

People's League of Health Test.—A test with less attention to detail was conducted on about 5,000 pregnant women in 1938–9 in London under the supervision of a committee appointed by the League.¹² Half the women were given daily supplements of calcium, iron, iodine, manganese, copper, and vitamins A, B, C, and D for periods of not less than 16 weeks before delivery. The findings were a significantly lower incidence of toxæmia and of premature births in the supplemented group than in the control group.

Other Tests.—It was formerly the custom to treat women showing signs of toxæmia with a low-protein diet or even a semi-starvation diet. The evidence just quoted casts doubt on the soundness of the basis for this practice. Recent observations by Arnell *et al.*¹³ make it even more dubious. They made observations on 400 pregnant women and found that 169 of them whose diets were much too low in protein—less than 54 g. daily—had lower haemoglobin and higher rates of general morbidity, of toxæmia, and of stillbirths than the remaining 231 women, whose diets were more satisfactory. Supporting evidence has been brought forward also by Burke,¹⁴ who kept dietary and clinical records of 216 women during pregnancy and the puerperium. The diets were rated "good," "fair," and "poor," and the incidence of toxæmia in the three groups was 0, 8%, and 44% respectively. The health of the babies was also graded, and it was found to be best in the "good" group. Stacey¹⁵ in a recent review says: "More deficiency states have resulted from this restriction than the good accruing from a liberal protein allowance in the diet."

Vital Statistics

Except for temporary setbacks in 1940–1, the maternal, infantile, and neonatal death rates and the stillbirth rate fell fairly steadily to the lowest levels ever.¹⁶ There are, of course, other factors besides food which can influence these rates, but the general environmental conditions and the facilities for medical care had deteriorated rather than improved during the war. Vital statistics for the 1914–18 war were not nearly so good. Between 1914 and 1918 neonatal mortality showed little change (39 and 36 respectively); infant mortality declined from 104 to 98, but maternal mortality rose from 5.1 to 7.6. Unlike in the late war, environmental conditions had not deteriorated, but the diet had.¹⁷ Table II shows the changes in consumption

TABLE II.—Changes in Consumption of Certain Foods during the Two Wars compared with Pre-war

	1913 v. 1909–13	1943–4 v. 1934–5
Milk	-26%	+25%
Eggs	-40%	-6%
Meat	-27%	-21%
Vegetables ..	-9%	+34%

of certain important foods during the two wars. The most important differences are for milk and vegetables. During the first war the consumption of milk fell by 26% and of vegetables by 9%; in the second world war milk consumption rose by 28% and vegetables by 34%. It is clear from these differences and from the others shown in the table that the national diet during the second war was far superior in constructive and protective nutrients to that during the first war.

Tuberculosis.—In regard to tuberculosis, the circumstances altered appreciably for the worse in the early part of the war. Many patients, who in peacetime would have remained in sanatoria, were sent home to make room for anticipated air-raid casualties. Many of these tuberculous people may have become infective after discharge, and the increase in the incidence of, and death rate from, tuberculosis in 1940–1 was not surprising.¹⁷ The death rate was 635 per million in 1938; it had risen to 699 in 1940, but had reached the lowest level ever—583 per million—in 1944. The incidence was 50,689 in 1938, 54,300 in 1943, and practically the same in 1944. The increased incidence is unquestionably, to some extent, a measure of improvement in ascertainment rather than in real incidence. Ascertainment was improved by the medical examination of large numbers of young people for military service, and by the introduction of mass radiography.

Increases in the incidence of, and mortality from, tuberculosis during the war have been reported from some European countries. Debré¹⁸ reported increased mortality rates of 38% to 74% in different districts of France in 1943, compared with 1935–8. The Institut National d'Hygiène¹⁹ reported that the increased deaths were confined mainly to urban and industrial areas, and that in some rural areas the death rate actually declined during the war. There is evidence, the source of which I cannot quote, that the diets of rural people in the occupied countries of Europe were generally well balanced and rarely below about 2,600 calories per head daily, whereas urban people in the same countries usually had ill-balanced diets, which were often well below 2,000 calories per head daily.

Tuberculosis has always flourished where there is poverty or famine, and it is generally believed that poor food is the dominant factor. The European evidence just quoted and the striking differences between the death rates during the first and second world wars support this view. During the first world war the death rate from tuberculosis rose from 1,340 per million in 1913 to 1,694 in 1918, whereas it decreased during the second world war. In a recent review Leitch²¹ has brought forward evidence indicating that diet plays a dominant part in maintaining the body's resistance against tuberculosis. There is therefore good reason to believe that the well-balanced diet during the war did a great deal to prevent increased mortality from tuberculosis.

Anaemia.—Before the war much attention was given to the incidence of anaemia among women of child-bearing age and young children, particularly of the poorer classes. The evidence of combined dietary and clinical surveys—e.g., those of Davidson, Orr, *et al.*²² in Aberdeen, of Charles and Magee²³ in Newcastle-upon-Tyne—has not always revealed a clear-cut relationship between the incidence of anaemia and the iron content of the diet. The anaemia which prevailed responded readily to iron therapy and was relatively rare in the better-fed sections of the population. There was justification, therefore, for believing that the anaemia was due to insufficient consumption of some nutrients, of which iron was believed to be the most important. Other nutrients—protein, the haemopoietic factors, calcium, copper, cobalt, and vitamin C—are known to be concerned in blood formation, but they were considered to be less implicated than iron in causing the nutritional anaemia found in this country. The relationship of vitamin B to nutritional anaemia has been the subject of many investigations, but they have not led to a definite conclusion. Recent work by Spies²⁴ suggests, however, that folic acid plays an important part in haemoglobin formation.

There does not appear to be general agreement as to what exactly constitutes anaemia. To some, haemoglobin below a certain level, somewhat arbitrarily chosen, is the chief criterion; others attach as much importance to signs and symptoms such as dyspnoea and asthenia. Like other biological characteristics, the haemoglobin level varies from person to person of the same

age, sex, and occupation, and the levels of a number of healthy people are always found to fall along a normal frequency-distribution curve. This was well brought out in the surveys of Price-Jones and others²⁵ in 1931 and 1935. They showed that the values for healthy men varied from 92% to 122% (Haldane). Since the subjects were healthy, we cannot regard 92% as any more abnormal than 122%, for a high haemoglobin is not necessarily a sign of health—it may mean quite the opposite. For instance, high haemoglobins are always found in polycythaemia, whether idiopathic or due to known causes—i.e., erythrocytosis. Anoxia is the normal stimulus to increased production of red cells, and this can arise from diminished oxygen in the air breathed, from pulmonary changes which impede the gaseous exchange in the lungs, or from impairment of the systemic circulation. Thus, erythrocytosis with correspondingly high haemoglobin is found at high altitudes, in heart disease (particularly mitral stenosis), and in pulmonary disease—e.g., emphysema. At heights of 14,000 feet, and in cardiac and pulmonary conditions of the above types, red cell counts of 7 to 8 millions and high haemoglobin values have been found.²⁷

Excluding such abnormal circumstances and conditions, variations of haemoglobin in healthy people may be explained to some extent by variations in the rate of blood-flow and in the efficiency of pulmonary aeration. The sedentary worker with sluggish circulation and shallow respiration may well require more haemoglobin than a person who lives a vigorous outdoor life. Price-Jones and his colleagues²⁸ thought that the higher haemoglobin they found in American men (112%) than in Englishmen (105%) might be due to breathing carbon monoxide, because all the Americans, but few of the Englishmen, possessed cars. Lack of exercise on the part of the Americans seems to me an equally plausible theory.

M.R.C. Haemoglobin Survey

The report of this survey of haemoglobin values²¹ shows variations between occupational groups which seem to lend support to the above theory. Tables VII and VIII of the report show the highest levels in men whose occupations involve little muscular exertion, and the lowest in those in occupations demanding much muscular work. For example, amongst the highest values for single men were: police office workers, 112%, civil servants 108%, laboratory workers 105%; amongst the lowest were: workers in textiles 96%, locomotive builders 97%, agriculture 99%. Similar differences were noted amongst married men, but the occupational differences for women, married and single, although showing the same trend, were not so marked as for the men. Thus married women workers in textiles had a mean of 85%, in agriculture of 93%, while laboratory workers had a mean of 95% and civil servants of 97%. Differences in diet are an improbable causal factor; any advantages there may have been were almost certainly on the side of the industrial and agricultural workers rather than of the sedentary workers, most of whom lived in cities. These occupational differences in haemoglobin values may well be an expression, in an inverse sense, of bodily vigour. It is obviously desirable that the precise cause of occupational differences should be settled, in order to place our interpretation of haemoglobin values on a more satisfactory basis than at present.

M.R.C. Survey Results.—The survey was undertaken at the request of the Ministry of Health. About 16,000 people of both sexes and of different ages and occupations all over the country were surveyed during 1943. The Haemoglobin Committee placed the normal value for the adult male at 105%, but it was unable to arrive at normal values for women and children of different ages. The report suggests, however, that values in women and children below 70% should be regarded as indicative of anaemia, and values between 70 and 80% as suggestive of anaemia. The Committee concluded that there was less anaemia than before the war, particularly in women and children. Since the survey was completed further evidence of decrease in the incidence of anaemia has been obtained by Fullerton²⁹; Dobbs, Mackay, and Bingham³⁰; and Davidson.³¹ It is difficult to conceive of any factor other than improvement in diet which could have produced such a remarkable change during the war.

Teeth and Gums

Teeth.—The dependence of the teeth on the nature of the diet for normality of structure and soundness is self-evident. Present teaching is that the diet of the mother during pregnancy and lactation is as important as that of the child itself after birth, for it would seem that the foundations of the teeth are laid *in utero*. Surveys of the condition of the teeth of 5-year-old children in East London were made in 1943 by Mellanby and Coumoulos¹¹ in the same schools in which Mellanby¹² had made a similar survey by the same methods on similar children in 1929. The teeth of the children in 1943 were found to be of sounder construction and to be less diseased than the teeth of their predecessors in 1929. Over one-fifth of the children in 1943 had caries-free teeth, compared with under one-twentieth in 1929. Reports of similar improvements have come from the School Dental Service. For instance, the Cambridge school dentist's report for 1944¹³ shows steady improvement during the war in the dental condition of school-children. The percentage of teeth showing decay in 5-year-old children was 20 in 1936, 22 in 1938, 14 in 1942, and 11 in 1944. The returns for Glasgow¹⁴ are even more striking. In 1938 only 18% of school entrants had mouths free from caries; in 1944 the proportion was 48%. It cannot be argued that this evidence of improvement was due to better dental hygiene; dentists were fewer and tooth-brushes were harder to get and more expensive than before the war. Then there were, particularly in London, the air raids and the disturbances and inconveniences they produced. It seems reasonable, therefore, to conclude that the improvement observed in the teeth of the children during the war years was due in no small measure to the better-balanced wartime diet.

One thinks naturally of the increase in consumption of calcifying factors—calcium and vitamin D—as the main cause of the improvement in the teeth of children, but it might be argued that decreased consumption of sugar was also a cause. Sugar consumption fell by about 9 oz. (253 g.) per head weekly compared with pre-war, but, for obvious reasons, there can be no certainty that the children actually consumed less sweets during the war. Moreover, King¹⁵ has recently produced evidence showing that supplements of sweets (1.5–3 oz., or 42.5–85 g., weekly) or of chocolate-coated biscuits (2 oz., or 57 g., weekly) given to children aged 3 to 4 years for 6 to 24 months had no effect on the teeth. The supplements were eaten just before the children went to bed, and after they had cleaned their teeth with tooth-brush and mouthwash, so as to give the acid products of carbohydrate fermentation ample opportunity to attack the teeth.

Gums.—Shortly after the outbreak of war there was an increase in the incidence of gingivitis, especially in and around military camps, where it had sometimes the prevalence of a minor epidemic. It was very prevalent among Gibraltarians in London in 1941, and King, Francklyn, and Allen¹⁶ obtained much success in treating them with a combination of local and systemic methods. Local treatment consisted in the removal of irritants and in the application of antiseptics; systemic treatment in the administration of niacin. King¹⁷ has therefore put forward the hypothesis that lowered resistance due to nutritional deficiency, particularly of the vitamin B₃ complex, often, but not always, plays a part in the causation of gingivitis. He, and several other observers, did not find ascorbic acid to have any effect on gingivitis, even when combined with local treatment. On the other hand, Campbell and Cook¹⁸ and some others, claim to have found ascorbic acid effective, and believe that too low consumption of ascorbic acid is a causal factor. The evidence, on the whole, suggests that ascorbic acid is ineffective against the gingivitis commonly found in this country, and it would seem that the B₃ complex is more likely than vitamin C to be at fault in those cases of gingivitis which are of nutritional origin. The bulk of the gingivitis seen at present is apparently of traumatic origin, unless, as with the Gibraltarians and others early in the war, change in environment, dietary habits, occupation, and mode of life causes some unusual strain on the organism as a whole. In this event the rate at which the vitamins are used up may exceed the intake, which, under more normal conditions, would be sufficient for maintaining health (see King¹⁹ for references).

Vitamins

Vitamin-feeding Tests.—During the war the notion prevailed in many quarters that concentrated preparations of vitamins—it did not seem to matter which one or ones—were a specific defence against war-weariness, anxiety, and strain, and that they were a tonic of particular value for what were called “war workers,” but people not so classified were not considered to have any special need of them.
